Late Paleogene–Neogene

ABSTRACT

We evaluate the topographic evolution of the southwestern Alps using Eocene to Pleistocene pollen data combined with existing sedimentological, petrographic and detrital geo- and thermochronological data. We report 32 new pollen analyses from 10 sites completed by an existing dataset of 83 samples from 14 localities situated across the southwestern Alps, including both the pro- and the retro-foreland basins. The presence of microthermic tree pollen (mainly *Abies*, *Picea*) indicates that this part of the mountain belt attained elevations over 1900 m as early as the Oligocene. Inferred rapid surface uplift during the mid-Oligocene coincided with a previously documented brief phase of rapid erosional exhumation, when maximum erosion rates may have reached values of up to 1.5–2 km/Myr. Slower long-term average exhumation rates of ~0.3 km/Myr since the Late Oligocene helped maintaining the high Alpine topography of the southwestern Alps until today. The relative abundances of meso-microthermic tree pollen (*Cathaya*, *Cedrus* and *Tsuga*) and microthermic tree pollen (*Abies*, *Picea*) in the pro- and retro-foreland basin deposits, indicate that the present-day asymmetric topography, with a relatively gentle western flank and steeper eastern flank, was established early in the southwestern Alps, at least since

[☆] **Author contributions:** All co-authors participated in writing the paper, in which S. Fauquette, J.-P. Suc, M. Bernet, S. Guillot and P. van der Beek took the lead. S. Fauquette performed the climatic and paleoelevation quantification based on pollen data; J.-P. Suc performed pollen counting on mosses and sediments and participated in field campaigns; A.S. Grosjean participated in field campaigns and worked on sediment provenance data; M. Bernet, S. Guillot, P. van der Beek, S. Jourdan, B. Pittet, P. Tricart, S. Schwartz participated in field campaigns; S.-M. Popescu performed pollen counting on mosses and participated in field campaigns; G. Jiménez-Moreno, A. Bertini and E. Roche performed pollen counting on sediments; Z. Zheng worked on the distribution of the taxon *Cathaya* and its ecological preferences; G. Pavia participated in field campaigns and sampling of mosses for modern pollen data; V. Gardien participated in sampling of mosses for modern pollen data.

the Early Miocene, and possibly since the Oligocene or Late Eocene. Therefore, the high topography and asymmetric morphology of this part of the Alps has been maintained throughout the past ~30 Ma.

1. Introduction

The topography of mountain belts reflects the combined effects and feedback relationships between tectonic processes, which cause crustal thickening and surface uplift, and climatically modulated surface processes, which create relief and tend to wear down mountainous topography (Willett, 1999; Whipple, 2009). Climate, in particular the amount, type and temporal distribution of precipitation, exerts a first-order control on weathering and erosion. The associated exhumation of rocks and mass redistribution at the surface influence the stress state and thermal structure of an orogen as part of the feedbacks within the system (Beaumont et al., 1992; Willett, 1999; Whipple and Meade, 2006). Different mechanisms have been proposed to explain the present-day topography and exhumation patterns of the European Alps, including crustal tectonics (Persaud and Pfiffner, 2004; Lardeaux et al., 2006), deep-seated geodynamic processes (Lyon-Caen and Molnar, 1989; Sinclair, 1997a; Lippitsch et al., 2003; Kuhlemann, 2007; Baran et al., 2014) or climatically induced processes. In particular the spatial coincidence of the highest rock-uplift rates in areas of the largest relief and the most deeply incised glacial valleys suggest that a significant part of the currently observed surface uplift is driven by the isostatic response to Quaternary glacial erosion of the mountain belt (Schlunegger and Hinderer, 2001; Champagnac et al., 2007; Vernon et al., 2009).

The tectonic record within the interior of the belt suggests a complex evolution with an exhumation signal that varies strongly both spatially and temporally (Garzanti and Malusà, 2008; Morag et al., 2008; Glotzbach et al., 2009; Jourdan et al., 2013). In particular, the exhumation history of the internal zones of the Alps, characterized by an Alpine metamorphic overprint, contrasts strongly with that of the external massifs (Vernon et al., 2008; Beucher et al., 2012). This evolution, however, appears smoothed in the regional detrital record, leading to an apparent constancy of exhumation rates recorded by detrital thermochronology data (Bernet et al., 2001, 2009; Glotzbach et al., 2011; Bernet, 2013).

Initial subaerial exposure and erosional exhumation of the internal zones of the Western Alps may have occurred during the climax of collision and major backthrusting of the internal zones at ~30 Ma (Fügenshuh and Schmid, 2003; Tricart et al., 2006) as well as overfilling of the peripheral foreland basins (Sinclair, 1997b; Ford et al., 1999; Pfiffner et al., 2002; Ford and Lickorish, 2004; Jourdan et al., 2012; Schwartz et al., 2012). A second major event took place during Early Miocene times, when extensional reactivation of the Oligocene frontal thrust (Penninic thrust) led to a shift in the locus of maximum surface uplift from the internal to the external zones of the Western Alps (Sue et al., 2007; Tricart et al., 2007). Surface uplift of the external crystalline massifs since this time (Leloup et al., 2005) led to drainage reorganization from a radial to the present longitudinal pattern and thus influenced sediment routing systems (Schlunegger et al., 1998; Kühni and Pfiffner, 2001).

We address two key questions: (1) What have been the magnitude and tempo of the elevation changes in the past? (2) Since when has the Alpine topography been comparable to the present-day?

Our reconstruction of the topography of the southwestern Alps since the onset of collision in the Late Eocene is based on the record of synorogenic pro- and retro-foreland basin (sensu Naylor and Sinclair, 2008) deposits of the southwestern part of the belt.

We use pollen analyses from Eocene and younger sediments coupled with previously published sedimentological, petrological, geochemical and geo-thermochronological sediment provenance and exhumation-rate data (Grosjean et al., 2012; Jourdan et al., 2012, 2013; Schwartz et al., 2012). We focus on two key phases, the Early Oligocene (~34–28 Ma), when collisional tectonics affected the entire mountain belt, and the Miocene (23.5–5.3 Ma), when major decoupling occurred between the external and internal zones along the Penninic front. The depositional age of the studied units is based on published biostratigraphic data and on climatostratigraphic correlation with other well-dated pollen floras from the northwestern Mediterranean (Suc et al., 1995a, 1999; Fauquette et al., 2007; Jiménez-Moreno and Suc, 2007; Bertini and Martinetto, 2008). Latest Messinian to Pleistocene pollen floras (Fauquette et al., 2006) have also been considered to provide insights on the topographic evolution through time.

2. Geological and morphological setting

2.1. Structure of the western Alps

The European Alps result from closure of the Alpine Tethys Ocean followed by continental collision between the European and Adriatic plates since ~35 Ma (Schmid et al., 2004; Rosenbaum and Lister, 2005). The structure of the belt is characterized by a complex nappe stack, involving both basement and cover rocks of the European margin, the intervening ocean (Piedmont zone) and micro-continents, and the Adriatic margin. The Penninic front, a crustal-scale thrust fault, separates the western Alps into an internal and an external domain (Fig. 1). The internal western Alps consist, from east to west, of (1) high-pressure/low-temperature metamorphic rocks of the internal crystalline massifs representing the most distal European margin (Dora-Maira, Gran Paradiso, Monte Rosa); (2) the Piedmont (“Schistes Lustrés”) zone; (3) medium to low-grade metamorphic rocks of the Briançonnais zone (European margin); (4) the non-metamorphic Helminthoid flysch nappes and (5) the obducted Chenailet ophiolite (Fig. 1). The external western Alps, to the west of the Penninic front, include the External Crystalline Massifs (Mont Blanc, Aiguilles Rouges, Belledonne, Pelvoux, Argentera-Mercantour), which consist of European basement rocks that were metamorphosed and intruded by granites during the Variscan orogeny, as well as Permo-Triassic to Cretaceous sedimentary cover rocks of the former European passive margin (Fig. 1).

2.2. Present-day topography

The present-day mean elevation of the western Alps is ~1500 m, with about 60 mountain peaks over 4000 m in the Mont Blanc, Valais, Monte Rosa and Pelvoux massifs (Fig. 2A). Local relief reaches between 2000–3000 m in the northwestern and 1000–2000 m in the southwestern Alps (Vernon et al., 2009). Although the highest summits and relief are associated with the External Crystalline Massifs, the internal zones have the highest average topography. Topographic profiles across the north-, central- and south-western Alps (Fig. 2B) show a clear asymmetric topography, with a steep eastern flank and a somewhat gentler western flank.

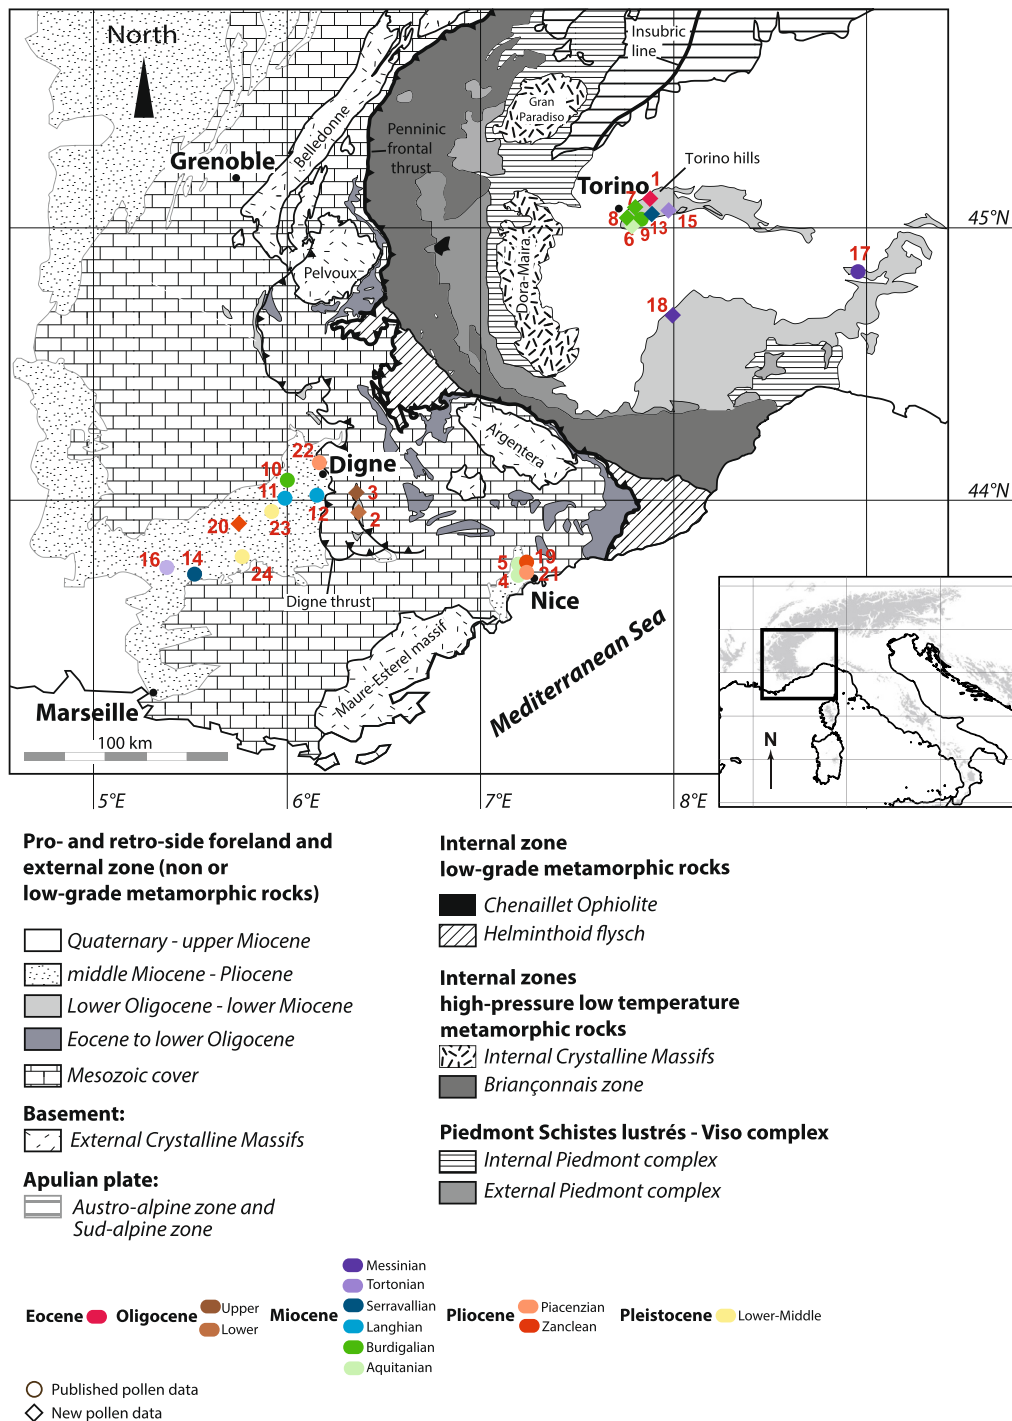

Fig. 1. Simplified geological map of the western Alps (modified from Jourdan et al., 2012) showing the location of the Paleogene to Neogene pollen sites. Pollen sites are numbered according to stratigraphic age: 1, Gassino Torinese; 2, Saint-Lions; 3, Gambi; 4, Le Gour; 5, Carros; 6, Tetti Civera 1; 7, Tetti Civera 2; 8, Tetti Civera 3; 9, Rio Civera; 10, La Rosée; 11, Les Mées 1 (borehole); 12, Châteauredon; 13, Pavarolo; 14, La Motte d'Aigues; 15, Borelli; 16, Vaugines; 17, Torre Sterpi; 18, Sioneri; 19, Saint-Martin du Var; 20, Villeneuve; 21, Saint-Isidore; 22, Le Rochassas; 23, Les Mées-Périgoite; 24, Oraison-Flour. New pollen data are indicated by a diamond and published pollen data by a circle.

3. Data and methods

3.1. Modern pollen records

Two transects were sampled across the southwestern Alps (Fig. 3 and Supplementary Table 1A) to obtain the pollen image of present-day vegetation. The pollen data (20 moss polsters and 2 recent lake sediments) are compared to the vegetation distribution along altitudinal and longitudinal gradients and are used as a

reference to interpret Paleogene to Quaternary pollen records. The moss polsters have been processed using KOH (10%), whereas lake sediments were treated with HCl and HF, both before sieving at 10 μm . Up to ~ 150 pollen grains were counted, excluding *Pinus* generally over-represented in pollen data.

3.2. Late Eocene to Mid-Pleistocene pollen records

We searched for pollen grains in clayey sediments (see Tables 1 and 2 for information on their deposition environment)

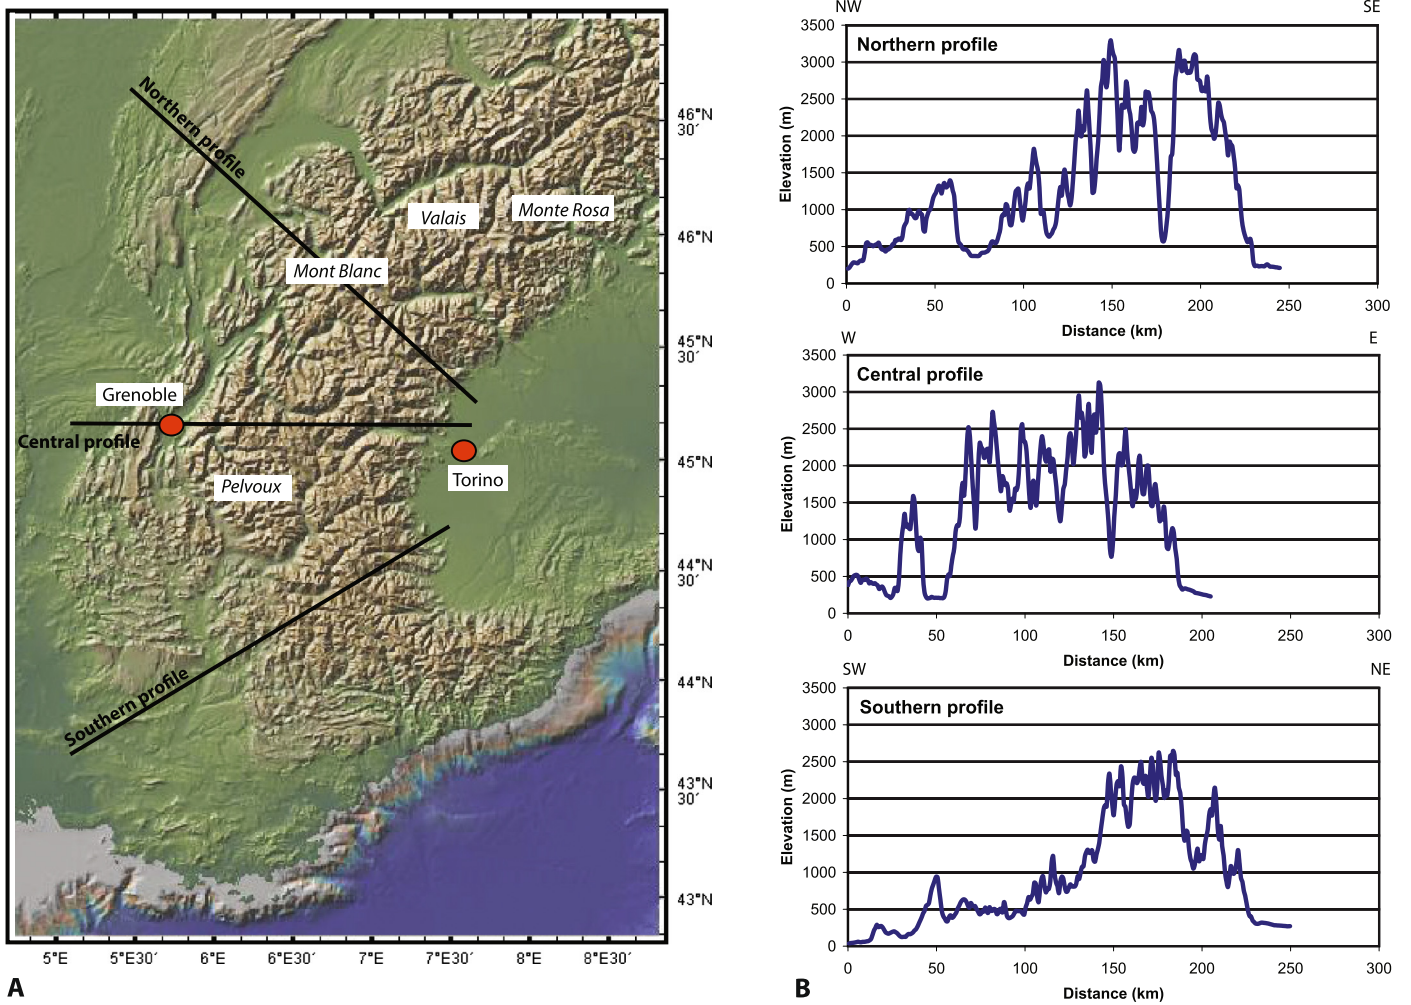

Fig. 2. A) Topographic map of the western Alps with the location of the areas with mountain peaks over >4000 m elevation (Mont Blanc, Valais, Monte Rosa, and Pelvoux) and B) three east–west profiles in the northern, central and southern parts of the western Alps. Particularly the northern and southern profiles show the asymmetric topography of the Western Alps with a steep eastern flank and a gentler western flank. The map was made with the GeoMap App (<http://www.geomapp.org>), using the Global Multi-Resolution Topography (GMRT) basemap (Ryan et al., 2009).

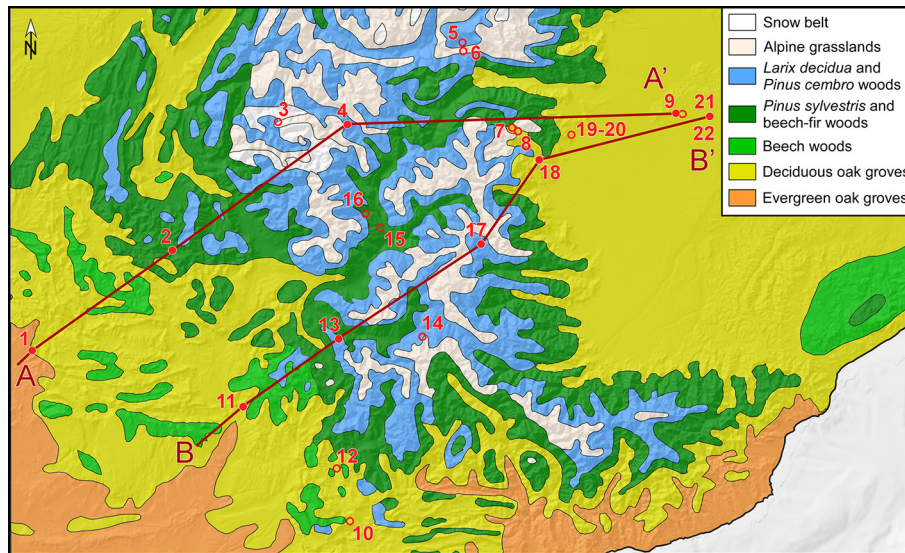

Fig. 3. Simplified vegetation map of the southwestern Alps (from Noirfalise et al., 1987) and position of the two transects along which modern pollen data were collected (localities on the transects are indicated by dots, localities out of the transects by circles). The relief of the map was added using the GeoMap App (<http://www.geomapp.org>) (Ryan et al., 2009). See Supplementary Table 1 for details on the localities.

Table 1

Results of the palaeo-elevation estimates for marine sediment sites. For each site we report the age and depositional environment of the sediments, the palaeolatitude based on the palaeogeographic maps of Meulenkamp and Sissingh (2003), the estimated mean annual temperature from pollen data (minimum, Most Likely Value, maximum MAT), the shift in altitude of the vegetation belts due to the differences in temperature with respect to the present-day, the most probable palaeo-elevations of the nearby massifs based on the Most Likely Values of MAT and, in brackets, ranges of palaeo-elevations based on the minimum and maximum MAT.

	Sites	Age	Depositional environment	Palaeo-latitude (°N)	MAT (°C) Min – MLV – max	Shift in altitude (m)	Microthermic trees in pollen records	Palaeoaltitude of nearby massifs
French slope	21 Saint-Isidore	Early Piacenzan	Marine, deltaic	Modern	14.8 – 17 – 18.2	+265 + 640 + 860	<i>Abies, Picea, Cathaya, Cedrus</i>	2040 m (1665/2260)

Table 2

Results of the palaeo-elevation estimates for non-marine sediment sites. For each site we report the modern elevation, the age and depositional environment of the sediments, the Most Likely Value of MAT, the contemporaneous flora living in lowlands used for the comparison and the palaeo-elevation of the site.

Non-marine sediment sites	Modern elevation (m)	Age	Depositional environment	MLV of MAT (°C)	Contemporaneous flora living in lowlands	Paleoaltitude of the sites
24 Oraison – Flour	408	Early Pleistocene	Fluvial loams	14.8	Semaforo (Southern Italy, Fauquette and Combourieu-Nebout, 2013)	420 m
23 Les Mées – Périgoite	522	Early Pleistocene	Fluvial loams	15.2	St Isidore (Southern France, Zheng and Cravatte, 1986)	330 m
22 Le Rochassas	820	Piacenzian	Palustrine	12		890 m
16 Vaugines	430	Tortonian	Palustrine	16.8	Mirabel (Naud and Suc, 1975)	~0

sampled close to coarser deposits in which mineralogical and thermochronological studies were performed previously. Most samples were collected from marine deposits of the foreland basins of the developing Alps, where abundant detrital sediments were supplied by the developing orogenic drainage system. In such sediments, pollen floras provide an unbiased record of the regional vegetation altitudinal belts, as established by studies on recent sediments (Heusser and Balsam, 1977; Heusser, 1988; Cambon et al., 1997; Beaudouin et al., 2005, 2007). A few samples have been collected in continental lacustrine, fluvial or lagoonal deposits.

Thirty-two new samples from 10 localities complete an existing dataset of 83 samples from 14 localities (Bessedik, 1985; Zheng and Cravatte, 1986; Zheng, 1990; Jiménez-Moreno, 2005; Suc et al., 1999; Hippolyte et al., 2011; Dubar, 1979). The total dataset thus contains data from 24 localities ranging from Late Eocene to Lower-Middle Pleistocene and distributed spatially on both flanks of the southwestern Alps (Fig. 1 and Supplementary Table 1B). Pollen identification following the botanical classification, based on high-level morphological examination, was accomplished at the finest possible taxonomic level by comparing the Paleogene and Neogene pollen grains with their present-day relatives using modern pollen collections. Percentages of taxa were calculated on the sum of the pollen grains and standard synthetic diagrams were drawn (Suc, 1984).

3.3. Methods for estimating palaeo-elevations using pollen data

The methods to quantify palaeo-elevations, developed by Fauquette et al. (1999) and Suc and Fauquette (2012) take into account pollen floras that provide a regional view of the vegetation from the lowermost up to the uppermost altitudinal belts within the drainage basin from which the sediments were sourced. The vertical shift of vegetation belts with latitude is obvious but difficult to quantify, as the altitudinal range of plant species is controlled by climatic parameters (decreasing temperature with altitude/latitude and concomitant increasing precipitation), but also by local conditions such as the nature of soils, slope orientation, etc. This organization of the vegetation was used by Ozenda (1975, 1989, 2002) to establish a standard relationship in which modern vegetation belts shift 110 m in altitude per degree in latitude (0.6 °C/° latitude vs. 0.55 °C/100 m elevation). This relationship seems to be valid for all mountainous massifs of the northern hemisphere, between 70 and 30 °N (Ozenda, 1989). The validity of the relationship is also demonstrated by detailed studies of the altitudinal limits of the vegetation in the Atlas Mountains of Morocco (Ozenda, 1975) and in the central Himalaya (Dobremez, 1972). The effect of the continentality may be important but our Neogene sites are situated in similar longitudinal position as the Alps today, so temporal variations in continentality will have been minimal. Therefore, using this altitude–latitude relationship together with the vegetation distribution and climatic estimates, palaeo-elevations may be assessed using fossil pollen records.

Microthermic trees inhabiting high elevation/high latitude zones, such as *Abies* and *Picea*, represent the best indicators of elevated topography in the fossil pollen floras. Based on modern marine sediments close to the Alps (Suc et al., 1999), a threshold value of ~3% for *Abies* and *Picea* has been used to infer the presence of forests of these taxa in the past (Fauquette et al., 1999). Nevertheless, pollen data do not allow estimating the altitudinal range of this vegetation belt, nor whether Alpine herbaceous and perpetual-snow belts existed above. This limitation is due to the difficulty of differentiating alpine herbaceous elements from those growing at lower elevations. As a consequence, these pollen-based palaeo-elevations are minimum estimates corresponding to the lower limit of the highest forested belt.

Palaeo-elevation estimates are based on the mean annual temperature (MAT) estimated at low elevations by excluding microthermic taxa from the reconstruction process (Fauquette et al., 1998). This low-elevation temperature is subsequently used as the base to estimate minimum elevation in the source area of the sediments using the full pollen spectrum and the relation between altitudinal and latitudinal temperature gradients inferred by Ozenda (1975, 1989, 2002). This procedure allows us to discriminate climatic variations from elevation changes.

Before the Tortonian, the latitudinal temperature gradient was weaker than the modern one in Europe; it was estimated by Fauquette et al. (2007) to be around 0.48 °C/° latitude during the Middle Miocene. We have similarly reconstructed the latitudinal temperature gradient for the Early Oligocene (Rupelian, 34–28 Ma) based on the MAT assessed from pollen records from significantly different palaeo-latitudes: Tongres, Belgium (50°46'N, Roche and Schuler, 1976) where MAT = 17.5 °C and Montauban, southern France (44°01'N) where MAT = 19.6 °C (Fig. 4 and Supplementary Table 2). We find that the Rupelian latitudinal temperature gradient was also weaker than the modern; around 0.46 °C/° latitude. Hypothesizing that the ratio between altitudinal and latitudinal temperature gradients was similar to the present ratio during these times results in Rupelian and Middle-Miocene altitudinal temperature gradients of ca. 0.42 °C and 0.44 °C/100 m, respectively.

Prior to the Pliocene, Europe was situated at lower latitudes than today (Fig. 4; Meulenkamp and Sissingh, 2003). The palaeo-latitudes of the sites for which we have pollen data have therefore been estimated from palaeogeographic maps.

Our method for estimating palaeo-elevation from pollen data has previously been successfully applied to Early Pliocene (5.3 Ma) marine sediments from the foot of the Mercantour Massif, south-eastern France, where it was validated by quantitative geomorphology (Fauquette et al., 1999). More recently, similar analyses have been applied to the Eastern Alps (Jiménez-Moreno et al., 2008), the Eastern Pyrenees (Suc and Fauquette, 2012) and the Apennines (Fauquette and Combourieu-Nebout, 2013; Fauquette et al., in press).

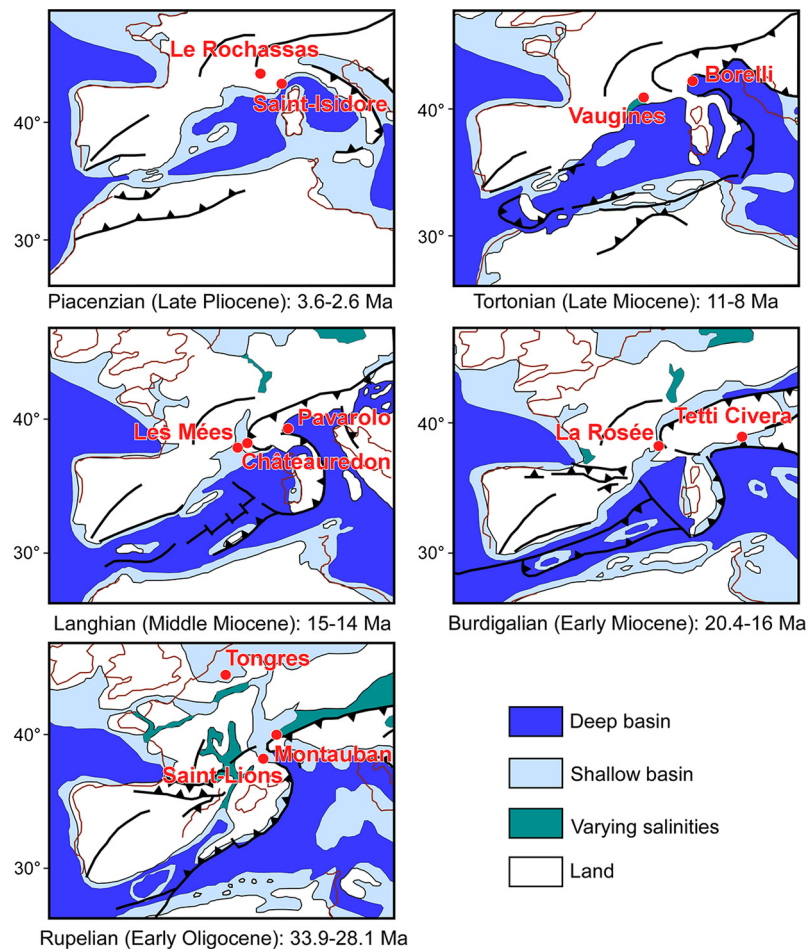

Fig. 4. Palaeogeographic maps (from Meulenkamp and Sissingh, 2003) with the position of the concerned sites for the late Rupelian, Burdigalian, Langhian, Tortonian and Piacenzian.

4. Results

4.1. Modern pollen flora transects

Vegetation is similarly organized in altitudinal belts on both flanks of the mountain belt except for the occurrence of the Mediterranean evergreen belt at low elevations to the west (Fig. 5). Vegetation belts are organized altitudinally according to the concomitant decrease in temperature and increase in precipitation, and are defined by their dominant plant element(s) (Noirfalise et al., 1987; Ozenda, 2002).

Pollen grains have been grouped as much as possible to correspond to vegetation belts (Fig. 5). However, several complications could not be avoided and require some explanation. First, *Pinus* has been separated because its pollen grain is not identifiable at the species level. Therefore, this genus may represent several vegetation belts, although its abundance in samples from the 'Larix decidua' and 'Pinus cembro woods' belt or close to it (sites 4, 5, 6, 13, 15; Fig. 5) allows considering a probable origin from this belt in such cases. Second, pollen grains of *Larix* are scarcely recorded; samples containing this genus were collected almost exclusively within its forests (sites 4, 5, 13, 15) or from sites immediately below such forests (sites 7, 8, 10, 12, 14, 16, 18). Third, pollen grains of Cupressaceae (rare except in site 22) are grouped because they cannot be identified at the genus level, even though their species grow at different altitudes (*Cupressus sempervirens* and *Juniperus oxycedrus* in the two lowermost vegetation belts, *J. communis* in the subalpine belt, *J. thurifera* at higher elevations). Fourth, most of the herbaceous pollen grains cannot be distinguished at an infra-

family level, whereas such plants can inhabit different altitudes; their abundance may indicate open (site 1) and/or undergrowth (sites 2, 3, 5, 7, 9, 14, 15, 18, 19, 20, 21) vegetation. Finally, alpine tundra-like plants (*Polygonum alpinum*, *Gentiana*, *Centaurea uniflora*) have been identified in some sites (4, 6, 13, 15), sometimes in large quantities. There, some other plants have been ascribed to this group by deduction such as *Alnus* ascribed to *A. viridis* and *Salix* to a dwarf willow despite our inability to identify them at the species level.

Wind transport may be important in mountainous regions and may lead to deposits recording pollen originating from other vegetation belts than that of the source area.

Despite these potential complications, the pollen data show a good correlation with the vegetation distribution along the slopes of the massifs and therefore faithfully record the different vegetation belts (Fig. 5). They also reflect the asymmetric elevation and therefore vegetation distribution along the two transects from west to east: the replacement of pollen groups as elevation increases appears progressive on the western flank but much more abrupt to the east (Fig. 5).

4.2. Late Eocene to Mid-Pleistocene pollen floras

Late Eocene to Pliocene pollen floras from both flanks of the southwestern Alps are characterized by prevalent megamesothermic plants (supporting subtropical conditions: MAT between 20 and 24 °C; Nix, 1982) and sometimes high frequencies of *Cathaya* (Fig. 6), a conifer living today in subtropical China at mid to high elevations, below the *Abies* and *Picea* belt (Wang,

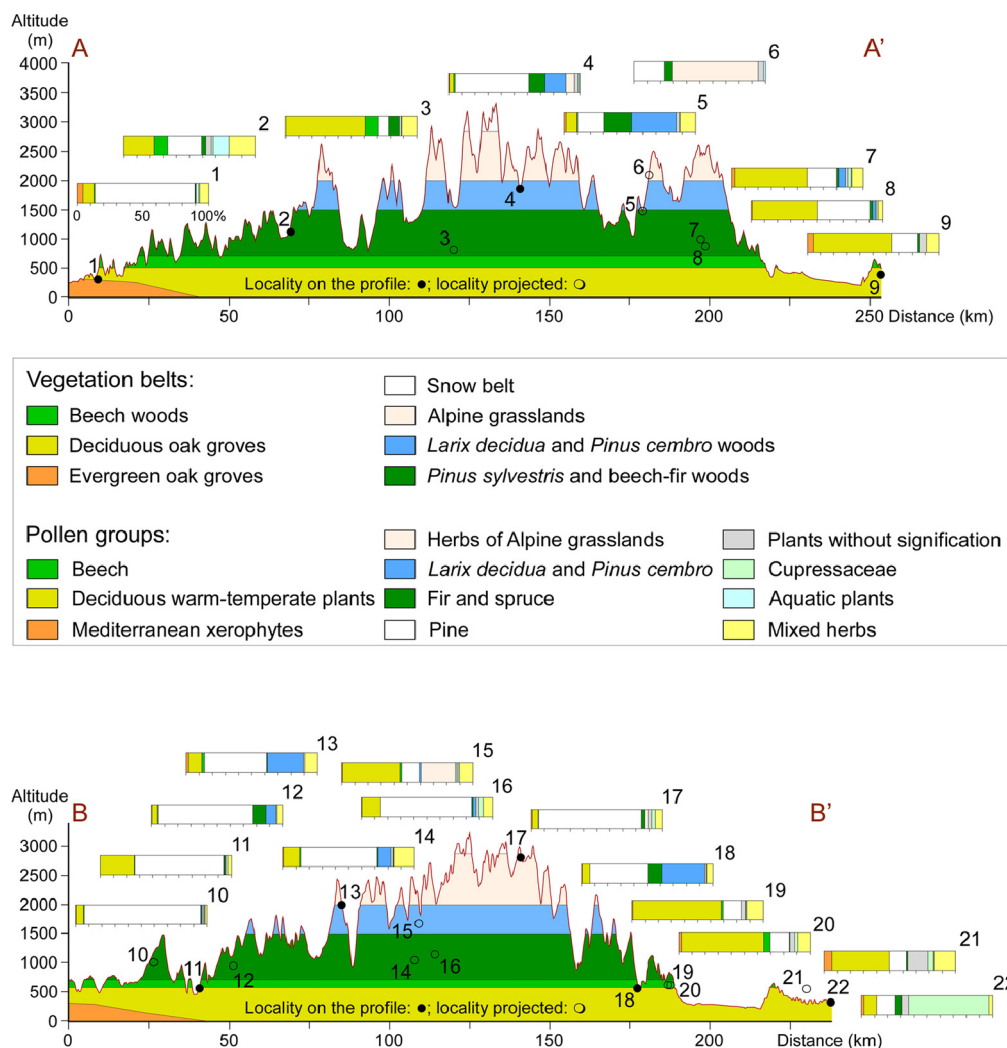

Fig. 5. Topography along the two transects of Fig. 3, position of the different vegetation belts (from Noifalaise et al., 1987; Ozenda, 2002) and relative proportions of pollen groups in the modern samples. Pollen localities are: Transect AA': 1, Nyons; 2, Luz la Croix haute; 3, Le Freney; 4, Col du Lautaret; 5–6, Mont Cenis; 7, Pinerolese (Lago Villaretto di Roure); 8, Pinerolese (Balma di Roure); 9, Baldissero Torinese (Val Samfrà). Transect BB': 10, Taulanne; 11, Clumanc; 12, Sisteron; 13, Saint-Léger; 14, Lac de Séguret; 15, Fournel; 16, Roche de Rame; 17, Agnel; 18, Inverso Pinasca; 19–20, Cappella della Colletta di Cumiana; 21 Baldissero Torinese; 22, Moncucco Torinese.

1961). Megathermic plants (supporting tropical conditions: MAT $>24^{\circ}\text{C}$; Nix, 1982) are present in all Eocene to Middle Miocene samples. The maximum frequency of such species was observed at Châteauredon the early Langhian age of which (Besson et al., 2005; Jiménez-Moreno and Suc, 2007) corresponds to the Mid-Miocene Climatic Optimum (~ 15 Ma; Zachos et al., 2001, 2008). Megamesothermic pollen grains decrease from the early Zanclean (~ 5 Ma) to the Piacenzian (3.6–2.6 Ma) (Fig. 6) and disappear from the pollen records at the earliest Pleistocene (2.6 Ma), probably due to the onset of Northern Hemisphere glaciations (Suc and Zagwijn, 1983; Suc, 1984; Bertini, 2010; Popescu et al., 2010).

On the whole, microthermic trees (supporting boreal conditions: MAT $< 12^{\circ}\text{C}$; Nix, 1982) such as *Abies* and *Picea* occur in significantly higher frequencies on the eastern flank (Tetti Civera, Pavarolo, Borelli) than in the west, except at Vaugines (late Tortonian), located at the foot of the Luberon Massif, where high percentages of *Abies* and *Cathaya* are recorded. From the Early Miocene to the beginning of the Tortonian, samples from the eastern flank also show a significant abundance of the meso-microthermic (supporting cool-temperate conditions: MAT between 12 and 14°C ; Nix, 1982) tree *Cedrus*, whereas at the same time *Cathaya* is the most frequent high-elevation tree recorded on the western flank (Fig. 6).

4.3. Palaeo-elevation estimates

The minimum estimated palaeo-elevation (corresponding to the lower limit of the *Abies-Picea* belt) is relatively well constrained for periods prior to the Pliocene, when climate was tropical to subtropical in Europe, because the uppermost vegetation belt was most likely forested rather than herbaceous. For the Pliocene-Pleistocene, the presence of alpine tundra-like vegetation is expected above the fir-spruce-larch forest. However, pollen data do not allow establishing the presence of an alpine herbaceous belt above the highest forest belt due to the difficulty of unambiguously discriminating high-altitude herbs from other herbaceous pollen. Palaeo-elevation estimates are thus minimum values, restricted to the lower limit of the highest forest belt. The results presented in Table 1 correspond to the most probable palaeo-elevations based on the Most Likely Values of MAT and, in brackets, to ranges of palaeo-elevations based on the minimum and maximum MAT.

Most of the sites to the east of the range (Tetti Civera, Rio Civera, Pavarolo, Borelli, Torre Sterpi, Sioneri; Fig. 1) record pollen grains of *Cathaya*, *Abies* and *Picea* (Fig. 6) indicating high palaeo-elevations within the nearby massifs. In Gassin Torinese (Late Eocene; Fig. 6) *Cathaya* is the only meso-microthermic tree present (Table 1), indicating an altitude between 950 and 1800 m. However, this is also the only site in our dataset that predates the

Fig. 6. Synthetic pollen diagrams for the Late Eocene to Pleistocene samples and their position in a chronostratigraphic frame (note the change of timescale at the Paleogene/Neogene boundary). Taxa have been arranged into thirteen different groups based on ecological criteria in order to visualize the main changes in the palaeo-vegetation cover at different altitudinal belts. Some groups are constituted according to thermic requirements of taxa with respect to the Nix (1982) classification based on the mean annual temperature (MAT): megathermic (tropical): $\text{MAT} > 24^\circ\text{C}$; mega-mesothermic (subtropical): $20^\circ\text{C} < \text{MAT} < 24^\circ\text{C}$; mesothermic (warm-temperate): $14^\circ\text{C} < \text{MAT} < 20^\circ\text{C}$; meso-microthermic (cool-temperate): $12^\circ\text{C} < \text{MAT} < 14^\circ\text{C}$; microthermic (boreal): $\text{MAT} < 12^\circ\text{C}$.

rapid Eocene–Oligocene cooling (Zachos et al., 2001; Hren et al., 2013). To the west of the southwestern Alps, the Oligocene Saint-Lions and Gambi sites (Figs. 1 and 6) indicate relatively high palaeo-elevations (1900 and 1740 m, respectively; Table 1). However, the other pre-Zanclean sites do not show significant percentages of *Abies* and *Picea*. In some sites (Châteauredon, La Motte d'Aigues; Table 1; Fig. 6) *Abies*, *Picea* and *Cathaya* are completely absent. Considering the La Motte d'Aigues site, this absence may be due to the long distance from high-elevation pollen sources. Data

from Châteauredon indicate the absence of high topography near this site. Early Zanclean to Early Piacenzian pollen data indicate high palaeo-elevations in the source areas, except at Villeneuve for which high-elevation trees are represented mostly by *Cathaya* (*Picea* < 1%; Table 1).

Table 2 displays the palaeo-elevation estimates for the continental sites. In this case, the estimated MLV of MAT from the pollen assemblage is compared to values inferred from a contemporaneous pollen flora representative of lowland vegetation.

The estimates correspond in this case to the palaeo-elevations of the pollen localities themselves. The analysis shows that the Late Pliocene–Pleistocene sediments of Oraison–Flour, Les Mées–Périgoite, Le Rochassas sites were deposited at their modern elevations of 408, 522 and 820 m respectively (Table 2). In contrast, the pollen assemblage from Vaugines (Tortonian), at the foot of the Luberon Massif (1125 m), indicates a very low elevation during deposition (Table 2); this site has therefore been uplifted later to attain its modern elevation of 430 m. However, the abundance of *Abies* and *Cathaya* in this pollen assemblage indicates nearby high elevations, estimated to be above 1670 m (Table 1).

5. Discussion

5.1. Limitations of the method

Numerous pollen studies (Roche and Schuler, 1976; Bessedik, 1985; Suc, 1989; Zheng, 1990; Suc et al., 1995a, 1995b, 1999; Jiménez-Moreno, 2005; Bertini and Martinetto, 2011) have shown that the European vegetation of the Mid-Cenozoic follows a similar latitudinal and altitudinal belting to that observed in present-day southeastern China (Wang, 1961) where most of the taxa that disappeared from Europe by the Late Neogene still occur today. One of the plants indicating the existence of significant palaeo-elevations in our pollen data is *Cathaya*. However, the use of this genus in palaeoenvironmental reconstructions is not straightforward as it is currently considered as a relictual plant. Modern *Cathaya* is a monospecific genus (*C. argyrophylla* Chun and Kuang) restricted to southern China (Wang, 1961). Eight populations have been recorded in four provinces (Guangxi, Hunan, Sichuan, Guizhou; Mao, 1989). They are found between 950 and 1840 m elevation at latitudes between around 24° and 29°N. Thus, the modern habitat of *Cathaya* is located ~10° more to the south than the palaeo-latitudes of the Cenozoic western Alps sites (Fig. 4). However, present-day isotherms are also shifted ~10° in latitude to the south in eastern China in comparison to Europe. For our reconstructions, we thus consider minimum and maximum elevations of 950 m and 1800 m, respectively, for *Cathaya*.

The altitude estimates of the sites were calculated using the Most Likely Values (MLV) of mean annual temperature (MAT) obtained from the pollen data. Although MLVs are less informative of climate than the entire reconstructed climatic amplitudes, as plants may sometimes support large climatic ranges, they provide a good estimation of the optimum conditions where the encountered plant assemblages best develop. Moreover, MLVs have been statistically tested on modern pollen data and are considered to provide reliable results (Fauquette et al., 1998). However, in order to provide an idea of the uncertainties, we also report the palaeo-elevation estimates based on the minimum and maximum MAT (in brackets in Table 1).

We combine our pollen data with multiproxy provenance analyses from the same detrital sediments (Jourdan et al., 2012), together with reconstructions of the drainage network (Grosjean et al., 2012) in order to better constrain pollen sources. We can use this data because studies on recent marine coastal sediments have established that the contribution of airborne pollen to these sediments is negligible in comparison to fluvially transported pollen (Cambon et al., 1997; Beaudouin et al., 2007).

5.2. Evolution of the western flank

Rupelian sediments sampled in the Barrême Basin at Saint-Lions (Fig. 1) were sourced from the internal Alpine massifs (Piedmont zone close to the modern Monte Viso and Briançonnais zones), whereas Chattian sediments from the nearby Gambi site are dominated by local clastic input mixed with a low proportion

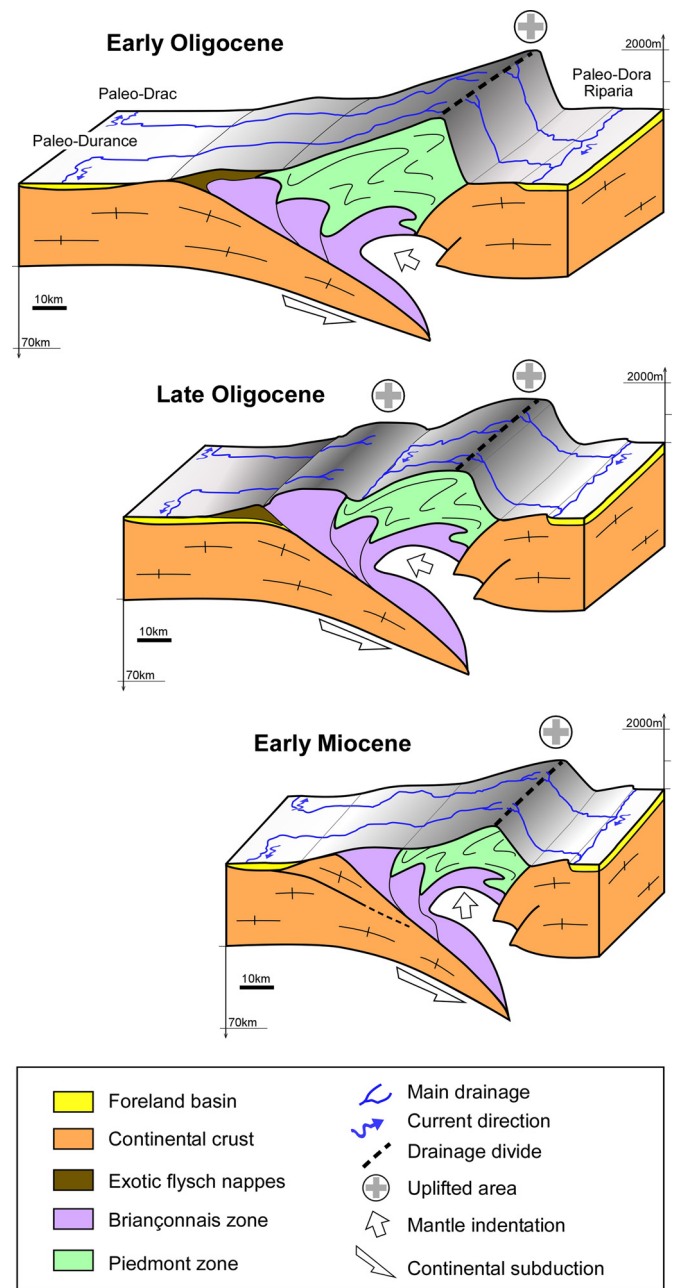

Fig. 7. Schematic reconstruction of the topographic and drainage evolution of the southwestern Alps from Early Oligocene to Early Miocene, showing the palaeo-Durance and the palaeo-Drac rivers draining the western flank of the main divide and the palaeo-Dora-Riparia draining the eastern flank.

of Alpine detritus (Evans and Mange-Rajetzky, 1991; Evans and Elliott, 1999; Morag et al., 2008; Jourdan et al., 2012; Schwartz et al., 2012). The pollen spectra from these sites include *Cathaya*, *Cedrus*, *Tsuga*, which indicate mid-elevations, as well as *Picea* and *Abies* indicating higher elevations, implying that as early as ~30 Ma, a nearby massif attained elevations around 1900 m (1100 to 2900 m according to the minimum and maximum MAT) near Saint-Lions and 1740 m (1100 to 2900 m) near Gambi. Given the configuration of the Oligocene drainage network (Fig. 7), in which both axial and transverse drainages were already established (Grosjean et al., 2012), the high-elevation internal zone of the southwestern Alps, around the present-day Monte Viso, would be the most logical source for these high-altitude pollen.

The Early-Miocene (Aquitanian–Burdigalian) sites of Carros and Le Gourge close to Nice (Fig. 1), show the presence of *Cathaya* and

Cedrus (Fig. 6) but insignificant percentages of *Abies* and *Picea*, implying the presence of an elevated massif in the source area during this time, the maximum elevation of which we estimate at 1800 m (Table 1). At present, the most proximal high-elevation massif for these sites is the External Crystalline Argentera-Mercantour Massif (Fig. 1). Using pollen data and quantitative geomorphological studies, Fauquette et al. (1999) showed that the Argentera-Mercantour Massif attained an elevation of ~2000 m during the Pliocene. The exhumation of the Argentera-Mercantour Massif is supposed to start at ~22 Ma (Corsini et al., 2004; Bigot-Cormier et al., 2006; Sanchez et al., 2011); it is therefore unlikely that the massif had already attained such high elevations in the late Early Miocene. An alternative source for pollen grains of microthermic and meso-microthermic plants encountered in Carros and Le Gourg samples would have been northern Corsica and the conjugate Maures-Estérel Massif, as previously suggested by Suc et al. (1992). Apatite fission-track data from northwest Corsica indicate rapid exhumation around 15–25 Ma, attributed to rift-flank uplift in response to Ligurian rifting during the Oligocene–Early Miocene (Zarki-Jakni et al., 2004; Danišik et al., 2007).

Several Burdigalian to Serravallian (~21–12 Ma) sites from the Durance Basin (La Rosée, Châteauredon, La Motte d'Aigues) do not record the presence of meso-microthermic and microthermic trees, except *Cathaya* (Fig. 6). Although the ages of La Rosée and Châteauredon overlap the Miocene Climatic Optimum (Jiménez-Moreno, 2005), during which vegetation belts would have risen, our palaeo-elevation estimates correct for this effect and indicate low elevations in the source areas (Table 1). This suggests that, first, the Digne thrust sheet which today overthrusts the Miocene Châteauredon series and develops topography of up to 1000 m in its hanging-wall, had not yet been emplaced at 15 Ma. Second, rivers draining the mountainous hinterland would not yet have reached the marine palaeogulf of the Durance Basin in the Middle Miocene. While the topmost part of the Châteauredon section (Valensole Conglomerates) clearly evidences transport by the palaeo-Durance river, the Middle Miocene sediments do not record alpine clastic inputs. This suggests that the modern Durance drainage network was established in the Late Miocene (Aguilar and Clauzon, 1982).

The analyzed sediments from La Motte d'Aigues post-date the Mid-Miocene cooling. However, the associated lowering of the vegetation belts is not recorded at this distal site. Only the pollen record from the Les Mées borehole encompasses the Mid-Miocene climatic extremes and shows a weak signal of the high-elevation conifers in its upper part (Fig. 6), probably recording their altitudinal descent due to global climatic cooling. Occurrence of high-elevation trees in these pollen records appears mainly controlled by the distance from the pollen source area and the organization of the drainage network.

The proximate early-Langhian Châteauredon and late-Piacenzian Le Rochassas sites bracket emplacement of the Digne thrust sheet and the modern drainage network to between ~15 and ~3 Ma (Hippolyte et al., 2011), as Le Rochassas samples indicate an elevation close to the modern elevation for this site (>800 m; Table 2) and provided a large amount of *Picea* pollen grains (Fig. 6), indicating the proximity of high topography. Likewise, pollen data from Villeneuve-Pigeonnier (Zanclean) show the presence of *Cathaya* among the meso-microthermic trees. *Picea* is present in insignificant percentages and *Abies* is absent (Fig. 6; Table 1). This indicates, that, in contrast to the Burdigalian/Serravallian period (~21–12 Ma), topography between 950 and 1800 m existed in the source area during the Early Pliocene. These results are also in agreement with inferred emplacement of the Digne thrust sheet during Miocene–Pliocene times (Jorda et al., 1988, 1992; Gidon, 1997; Fournier et al., 2008).

Finally, in the Serravallian (~12–13 Ma) La Motte d'Aigues site, located <15 km from the Luberon Massif, the absence of high-

altitude tree pollen grains indicates that the Luberon Massif had not yet attained high elevations at that time. In contrast, high percentages of *Abies* pollen grains (~31%) in the middle Tortonian (~9 Ma) Vaugines site, at the base of the Luberon Massif, show that high topography existed in the source area of this site, which is situated within a syncline filled by Miocene sediments derived from erosion of the Luberon anticline crest (Clauzon et al., 2011). Thus, our data is consistent with structural and topographic development of the Luberon Massif by south-directed thrusting during the time interval 10–6 Ma, as suggested by Clauzon et al. (2011).

The site of Vaugines is today at 430 m elevation, whereas during the middle Tortonian it was near sea level (Table 2). High temperatures during the Miocene (MAT between 10 and 23 °C, MLV around 17 °C) led to a positive shift of around 300 m of the vegetation belts (Table 1). In southern France, the lower altitudinal limit of the *Abies* belt is currently at 1400 m. Therefore, the occurrence of *Abies* in the Vaugines samples indicates source-area elevations above ~1700 m in the Tortonian, while the maximum elevation of the modern Luberon Massif is 1125 m a.s.l. Our results therefore imply that ~600 m surface lowering of the massif by erosion occurred since the Late Tortonian, whereas the foreland was uplifted by ~400 m.

Overall, sites from the western flank indicate the existence of high topography within the internal zone of the southwestern Alps since at least the Early Oligocene, together with outward propagation of deformation and structuring of the foreland during Late Miocene–Pliocene times (Fig. 7). This finding is consistent with the westward migration of the main drainage divide between the Oligocene and Miocene inferred by Jourdan et al. (2012) from provenance data. All Late Oligocene to Miocene sites containing marine deposits are today several hundred meters above sea level, up to 855 m for Gambi. Thus, surface uplift of the western foreland must have taken place during the Neogene and Early Quaternary.

5.3. Evolution of the eastern flank

Late Eocene (~37–34 Ma) clays sampled near Gassino Torinese belong to the Monte Piano Formation of the Torino Hills and are considered as distal Alpine deposits (Festa et al., 2011). The presence of *Cathaya* and the absence of *Abies* and *Picea* in these samples suggest palaeo-elevations of 950 to 1800 m. Jourdan et al. (2013) show that these early deposits in the Torino Hills were derived from the internal western Alps, suggesting the existence of proto-relief in this area already eroded by a palaeo-Dora Riparia drainage system (Fig. 7).

The sites in the Torino Hills that cover the Early to early Late Miocene (Tetti Civera, Rio Civera, Pavarolo, Borelli) indicate high palaeo-elevations of the nearby massifs, from >1680 m (1300–2250 m) during the Aquitanian (~23–20.5 Ma) up to >1925 m (1465–2900 m) during the mid-Tortonian (~10 Ma). Pollen data from Torre Sterpi and Sioneri, covering the latest Messinian (~6 Ma), indicate a minimum elevation around 1800 m (1400–2800 m). However, we interpret this apparent lowering of the minimum elevation of the massif compared to previous periods as an artefact, due to the comparatively colder climate during Pliocene times and associated lowering of the *Abies* vegetation belt.

Thus, our pollen data from the eastern flank of the southwestern Alps suggest continuous high minimum elevations (of the order of 1800 m based on the MLV of MAT), since at least the Early Miocene and possibly since the Late Eocene.

5.4. West–East dissymmetry in topography

Late Paleogene and Early Neogene pollen spectra from the western flank of the southwestern Alps contain relatively high percentages of *Cathaya*, with respect to *Abies* and *Picea*. Likewise, Late

Neogene samples contain relatively high percentages of *Cedrus* and *Tsuga* with respect to *Abies* and *Picea*. Conversely, the sites on the eastern flank show a relative balance between meso-microthermic (*Cathaya*, *Cedrus* and *Tsuga*) and microthermic (*Abies* and *Picea*) tree pollen.

This asymmetry between the two flanks of the mountain belt could be interpreted as a difference in temperature, the eastern flank being cooler than the western one. However, such an interpretation is contradicted by an equivalent abundance of megathermic and mega-mesothermic plants on both flanks (Fig. 6). The different proportions of meso-microthermic versus microthermic tree pollen are better explained by shorter pollen-transport routes from high elevations to the sedimentary sinks towards the east than towards the west, as also observed in the present-day pollen records (Fig. 5).

Pollen data from the western flank imply that the lowest conifer belt, constituted by *Cathaya*, *Cedrus* and *Tsuga*, was close to the sites of deposition and widely developed in space, and that a higher conifer belt constituted by *Abies* and *Picea* was far from these sites. This organization of the vegetation belts supports a relatively progressive increase in elevation on the western flank, as today (Fig. 2B). In contrast, pollen data from the eastern flank imply that both the lower and higher conifer belts were close to the Torino Hills sites, supporting an abrupt increase in elevation on the eastern flank of the southwestern Alps (Figs. 2B, 7). Therefore, the present-day topographic asymmetry of the southwestern Alps dates back to at least the Early Miocene, and possibly to the Oligocene or Late Eocene.

5.5. Topography and exhumation

In many orogenic belts, high topography is associated with high relief and erosion/exhumation rates (Montgomery and Brandon, 2002), as reflected by the present-day topography and exhumation patterns of the western Alps (Vernon et al., 2009). Unfortunately it is impossible to directly determine palaeo-relief from pollen or provenance data. Even though, in theory, detrital thermochronology data may allow information on palaeo-relief to be extracted (Stock and Montgomery, 1996), in practice the data are generally insufficiently resolved to permit this (Beucher et al., 2012; Olen et al., 2012). We know from previously published geo- and thermochronologic data (Bernet et al., 2009; Jourdan et al., 2013) as well as provenance studies (Evans and Mange-Rajetzky, 1991; Jourdan et al., 2012; Schwartz et al., 2012) that, during the Early Oligocene, local peak exhumation rates briefly increased to 1.5–2 km/Myr in the southwestern Alps (Morag et al., 2008; Jourdan et al., 2013), but average long-term exhumation rates remained much lower (~0.3 km/Myr) and fairly constant since ~27 Ma (Bernet et al., 2009). The timing of the peak exhumation rates during the Early Oligocene appears to coincide with the formation of high topography in the southwestern Alps. The slower long-term average exhumation rates would then reflect the persistence of this topography and its asymmetry until today. The westward shift of the southwestern Alps drainage divide during the Oligocene, as proposed by Jourdan et al. (2012) (Fig. 7), and the recent (<2 Ma) glacial modification of high topography in the western Alps (Glotzbach et al., 2013) are superimposed on this overall stable topographic setting.

5.6. Geodynamic implications

Von Blanckenburg and Davies (1995) proposed that in the northwestern and Central Alps slab break-off occurred between 35 and 30 Ma, driving the major and well-documented change from flysch to molasse deposition in the foreland basin at that time (Sinclair, 1997b). The seismic tomography data of Lippitsch

et al. (2003) provide support for a slab break-off event, whereas Duretz et al. (2011) developed a theoretical framework for linking slab break-off and the topographic evolution of the western Alps. These authors state that intermediate slab break-off at the oceanic-continental lithosphere transition causes surface uplift of the overriding plate at a rate of 0.5 km/Myr after ca. 1 Ma, which is partly compatible with the inferences from detrital thermochronology data (Jourdan et al., 2013). Slab break-off followed by surface uplift is synchronous with anticlockwise rotation of the Apulian plate, a change in the convergence direction from south-north to east-west between the Apulian and Eurasian plates, and crustal thickening during continent-continent collision, which all started at about 35–30 Ma (Handy et al., 2010; Malusà et al., 2011; Dumont et al., 2012). This generalized and sharp kinematic change is linked to slab retreat in the nascent Mediterranean realm, inducing strong westward mantle flow beneath the southwestern Alps (Jolivet et al., 2009). However, while slab break-off can account for a general uplift of the Alps during the Early Oligocene, it cannot explain the localized uplift and the dissymmetry recorded at that time in the western Alps.

Theoretical models of doubly-vergent critical wedges (Willett et al., 1993; Whipple and Meade, 2006) predict that the retro-wedge should be steeper than the pro-wedge, consistent with the palaeo-elevation and exhumation record of the southwestern Alps (Carrapa, 2009; this study). Moreover, geophysical analyses of the deep structure of the Western Alps show the presence of the high-velocity, high-density Ivrea body in the core of the orogenic arc, at less than 10 km depth (Schmid and Kissling, 2000; Paul et al., 2001; Lardeaux et al., 2006). The Ivrea body, which is interpreted as a sliver of Apulian mantle, acts as a vertical indenter against the European plate during east-west convergence (Lardeaux et al., 2006). This indenter may have supported localized surface uplift in the internal western Alps and further explain the topographic dissymmetry recorded by sediment provenance (Schwartz et al., 2012; Jourdan et al., 2012, 2013; Fig. 7).

Sites from the western foreland show significant (up to 800 m) surface uplift since the Late Miocene (Section 5.2). Up to 500 m of foreland uplift can be attributed to the flexural isostatic response to increased Quaternary erosional unloading of the western Alps (Champagnac et al., 2008), which would lead to net surface lowering of the mountain range. The remainder could possibly be attributed to deep-seated geodynamic processes, such as renewed slab break-off (Kuhlemann, 2007; Baran et al., 2014), for which geophysical evidence remains scarce, however (Lippitsch et al., 2003).

6. Conclusions

We show that the topography of the internal zone of the southwestern Alps could have reached elevations around 1800 m as early as the Oligocene (~30 Ma). In contrast, the external massifs, including the Mercantour Massif in the southwestern Alps, were uplifted later, during the Late Neogene, while emplacement of the external Digne thrust nappe occurred after the Serravallian (~12–13 Ma). Pollen data show that the present-day topographic asymmetry of the southwestern Alps, with a relatively gentle western flank and much steeper eastern flank, dates back to at least the Early Miocene, and possibly to the Oligocene or Late Eocene.

This topographic evolution is coherent with provenance data and estimates of exhumation rate from detrital thermochronology from the same sedimentary units in the pro- and retro-foreland basins. Rapid surface uplift during the Early Oligocene coincided with a brief episode of rapid exhumation; the high topography of the internal zones of the southwestern Alps has been maintained with moderate long-term average rates of exhumation since that time. Westward propagation of deformation in the Miocene-

Pliocene and Quaternary glacial erosion has not severely perturbed this overall stable system.

Acknowledgements

This is a contribution to the project “Erosion and Relief Development in the Western Alps” funded by the Agence Nationale de la Recherche (ANR-08-BLAN-0303-01). Information on *Cathaya* has been collected during the Project T00-04 of the Association Franco-Chinoise pour la Recherche Scientifique et Technique. J.-L. de Beaulieu is acknowledged for providing some modern pollen analyses and S. Ferry for sampling some mosses. Two anonymous reviewers helped us to improve the manuscript. This is ISEM contribution n°2014-229.
