Abstract

Allanite is a major host of rare earth elements (REE) in the continental crust. In this study, reaction mechanisms behind allanite alteration are investigated through batch experiment runs on natural allanite grains in carbonate-bearing hydrothermal fluids at 200 °C, with initial acidic (pH=4) or alkaline (pH=8) conditions and with different aqueous ligands (120 mM of F, Cl, P or S). Time-series experiment runs in F-doped systems at different durations between 15 and 180 days reached a steady state at 120 days. The pH efficiently controls the allanite alteration process, with initial high pH, alkaline conditions being more reactive (75% alteration compared to 25% under acidic conditions). The ligand also significantly influences the alteration process under initial acidic conditions with P-doped system (70%) almost non-reactive for the Cl- and S-doped systems (< 5%). In the alteration rim, REE are mainly redistributed in REE-bearing phases either as carbonates (F-doped) or phosphates (P-doped). The relatively flat REE-normalized patterns of the recovered experimental fluids suggest a fractionation of LREE over HREE during the course of the alteration reactions. It is proposed that secondary REE-mineral precipitation at the reaction front creates a local disequilibrium in the solution and a steep chemical gradient promoting allanite dissolution and thus its alterability.

1 Introduction

Allanite, a mineral of the epidote group with the ideal formula $CaREEFe^{2+}(Al, Fe^{3+})_2(Si_2O_7)(SiO_4)O(OH)$, is a major REE-carrier mineral in the continental crust, with preferential incorporation of the light REE (LREE: La to Gd) over the heavy REE (HREE: Tb to Lu + Y). Primary allanite occurs as an accessory phase in magmatic and metamorphic rocks (Gieré and Sorensen, 2004 and references therein). It is a good petrological proxy and geochronometer for metamorphic processes (e.g. Engi et al., 2017), magma sourcing (e.g. Anenburg et al., 2015), or mineralisation under hydrothermal conditions (e.g. Pal et al., 2011). Allanite has also been described as the main primary REE and U source in supergene and hydrothermal systems (Caruso and Simmons, 1985; Berger et al., 2008; Ichimura et al., 2020), reaching economic levels (Chabiron and Cuney, 2001; Corriveau et al., 2007). Hydrothermal alteration of allanite is common (Poitrasson et al., 2002) and often occurs as partial replacement of primary allanite by secondary REE-minerals. These include fluorocarbonates (e.g. Middleton et al., 2013), phosphates (Berger et al., 2008), and silicates (Smith et al., 2002). Frequently, secondary Th-minerals are also described in association with allanite replacement (Buda and Nagy, 1995; Middleton et al., 2013). As a main REE-host, these alteration reactions are thus important for understanding REE mass transfer, with their economic implications as strategic metals. Furthermore, understanding associated actinide mobility in REE-rich hydrothermal systems is also crucial, because it can be decisive for REE-mining (as by-products or nuclear waste).

It is widely accepted that the greater sensitivity of allanite to alteration, compared to that of epidote (Price et al., 2005), is partly due to its metamict state, which is caused by α-particle bombardment damaging the structure, even for a low Th and U content (Ewing et al., 1987; Ercit,

55 2002). The role of other inherent factors, such as the crystal chemistry of the allanite and the

56 physicochemical properties of the fluid, remains poorly understood. While numerous examples

57 of natural allanite alteration have been reported, its experimental reactivity in the presence of

58 hydrothermal fluids has received little attention, only at high pressure and high temperature

59 conditions (Krenn et al., 2012) or as a product of monazite and xenotime alteration (Budzyń et

60 al., 2011; 2017). In order to fulfil this gap, allanite alteration experiments have been conducted

61 on natural homogeneous crystalline grains in the presence of carbonate-bearing hydrothermal

62 fluids doped with various ligands (120 mM of F, Cl, P, S) under initial acidic and high pH alkaline

63 conditions at 200 °C and P_{sat} for durations from 15 to 180 days. The role of added ligands was

64 investigated for initial acidic conditions, (pH around 4 at room temperature), common under

65 hydrothermal conditions (Seward et al., 2014). The investigated ligands are elements of

66 importance for REE mobility in hydrothermal systems due to strong aqueous complexation at 200

67 °C (Gammons et al., 1996; Migdisov and Williams-Jones, 2002, 2008; Migdisov et al., 2009).

68 The kinetics of the alteration reactions were investigated through time-dependent experiments

69 using both acidic and high pH alkaline fluids, (pH = 8 at room temperature), in the presence of F.

70 In this study, the experimental alteration of allanite is strongly controlled by the fluid composition

71 and the precipitation of secondary REE-minerals in the form of fluorocarbonates and phosphates.

72

2 Analytical methods and experimental procedure

2.1 Starting material

All experiments were performed using fragments from a monocrystal of allanite ~~(20 mm~~ Ce (henceforth allanite) from the Frontenac formation in the Central Metasedimentary Belt of the Greenville Orogen (Ontario, Canada). Crystallisation ages, based on associated titanite U-Pb geochronology, ~~range from~~are around 1157 - 1178~~ to 1157~~ Ma (Mezger et al., 1993). The composition, determined by EPMA, is homogeneous, and corresponds to an intermediate composition between ferriallanite and allanite, with a general formula: $Ca_{1-1.2}REE_{0.6-0.8}Al_{1.5-1.7}Fe^{3+}_{0.1-0.5}Fe^{2+}_{0.8-1.1}Mg_{0.1}Si_{3.1-3.3}O_{12}(OH)$ (Table S1, supp. mat.). Radionuclides contents ~~are~~range such as 0.~~53~~36-0.79 wt.% ThO_2 and ~~0.06 wt.%~~ UO_2 mostly below detection limit.

The crystal was crushed manually and then grinded mechanically using a planetary micro-mill Fritsch Pulverisette 7. To ensure maximized kinetics and yet a suitable grain size for post-experimental characterization, we selected an initial grain size of 20-50 µm after sieving. Traces of REE-carbonates in micro-cracks (observed by SEM but not detected on X-ray diffraction pattern) were removed by soaking the allanite powder in a 1M acetic acid solution in an ultrasonic bath for 10 min. After centrifugation (3500 rpm, 10 min), the solid residue was filtered through a 2.7 µm glass fibre filter and dried overnight at 50°C. The material was stored in spectroscopic plastic tubes in the dark at ambient temperature.

2.2 Experimental procedure

Experiments were conducted by reacting 150 mg of powdered allanite (Fig. S4, supp. mat.) with 1.5 mL of the aqueous solution (fluid/solid ratio = 10) in 3 mL Teflon cell reactors sealed into a steel autoclaves without agitation ("static batch reactor") and placed in a multi-oven at 200 °C ($P_{sat} \approx 16$ bar or 16 bar + pCO_2, when CO_2 was added). However, pCO_2 varies during alteration and these variations were not quantified. Acidic solutions with an initial pH = 4 were obtained by adding to ultrapure water 99.9% certified pure carbonic ice (around 30 mg). For alkaline systems, ultrapure water was replaced by 1.5 mL of a 1 M $NaHCO_3$ solution (pH = 8.7, Lafay et al., 2014). These solutions were mixed with 120 mM, (equivalent of the REE molar content in allanite),) of F, (introduced as solid NaF), P (as Na_3PO_4., 12H_2O), S (as Na_2SO_4) or Cl (as NaCl). A first time series of experiments using NaF as ligand in acidic and alkaline systems was performed (15, 30, 60, 120, and 180 days) to investigate the kinetics of the reaction processes (**Table 1**). Experiments with other ligands were run for 120 days. At the end of each experiment, the sealed reactor was rapidly quenched in cold water. Recovered solutions were carefully collected with a syringe, filtered to remove solid residue (0.2 μm), diluted 5 times in ultra-pure water slightly acidified with nitric acid and immediately stored at 4 °C in a ion-free ion tube for further characterization. Residual solid was collected, dried at 60 °C for one night, weighted and stored at ambient temperature. A fraction of each solid run product was mounted in epoxy resin and finely polished (mirror surface) for microscopic and electron microprobe analyses.

2.3 Solid characterization methods

2.3.1 X-Ray Diffraction (XRD) and Rietveld refinement

Mineral modal abundances of initial and post-experimental solids were characterized by XRD at ISTerre (Grenoble, France). Samples were grounded in ethanol using a McCrone micronizing mill, oven-dried overnight and prepared as a randomly oriented mount. The XRD patterns were recorded with a Bruker D8 powder diffractometer equipped with a SolXE Si(Li) solid state detector from Baltic Scientific Instruments using CuKα_1+2 radiation. Intensities were recorded at 0.026° 2θ step intervals from 5 to 90° (10 s counting time per step). Eva Bruker software associated with the ICCD pdf database was used to determine the modal composition of the powder on a significant part of the recovered solid product for all alteration experiments. This enables to distinguish between the different REE-minerals in the solid product. Rietveld refinement with Profex/BGMN software was then performed to precisely quantify mineral abundances. The quality of the Rietveld refinement is assessed by the χ^2 factor, which lies between 2.5 and 4 for all experiments.

2.3.2 Scanning Electron Microscopy (SEM)

The mineral distribution and microstructure of the experimental solids were investigated by using a ZEISS Gemini 500 SEM. The measurements were carried out in high-vacuum mode using a high tension (EHT) of 3 kV for a working distance (WD) between 3.4 and 4.8 mm. Samples were sputtered with a 15 nm thick cover of Au-Pd. Complementary investigations were performed using the conventional environmental SEM Tescan Vega 3. The measurements were

133 carried out in high-vacuum mode (9.9 ~~x~~ $\times$ 10^{-9} bar), using an accelerating voltage of 16 kV, with

134 90 nm spot size and 15 mm working distance. Samples were sputtered with 20 nm of carbon.

135 The microscope is equipped with a 30 mm^2 Energy Dispersive X-Ray Spectroscopy (EDS)

136 manufactured by Rayspec with SamX's electronic system and software.

137

2.3.3 Electron probe micro-analyser (EPMA)

139 Quantitative chemical analyses of initial and post-experimental allanite and secondary

140 products (when the grain size was suitable) were carried out using a JEOL JXA-8230 electron

141 probe micro-analyser (EPMA) equipped with five wavelength-dispersive spectrometers (WDS)

142 at ISTerre (Grenoble, France). Analytical conditions were 15 kV acceleration voltage, 12nA beam

143 current, and 1 to 5 μm beam size (details in Table S3, supp. mat.). The ZAF correction procedure

144 was applied using the JEOL software for quantitative analysis. The detection limits range between

145 0.01 and 0.04 wt% using the 2σ criterion (Batanova et al., 2018).

146

2.3.4 Trace element analysis (LA-ICP-MS)

148 Trace element analysis of allanite was performed at the Institute of Geological Sciences

149 (University of Bern) using a laser ablation inductively-coupled plasma mass spectrometry (LA-

150 ICP-MS), which consisted of a Geolas Pro 193 nm ArF excimer laser coupled to an Elan DRC-e

151 quadrupole ICP-MS. A He-H_2 gas mixture (1 and 0.008 L/min respectively) was used as the

152 aerosol transport gas. Allanite trace element analyses were performed with laser beam diameters

153 of 16, 24, and 32 μm, frequencies of 9 and 7 Hz, and energy densities on the sample of 5.0 J/cm^2.

154 Sample analyses were calibrated using GSD-1Gg and accuracy was monitored using a reference

155 glass NIST glass SRM 612 (Jochum et al., 2005, 2011). Data reduction was performed using the

156 SILLS software package (Guillong et al., 2008) and LOD values obtained with the method of

157 Pettke et al. (2011).

158

2.4 Fluid characterization methods

159

2.4.1 Inductively-coupled Plasma Spectrometry

160

161 All recovered solutions were stored using metal-free tubes (VWR). For an accurate

162 quantification of trace elements, measurements were performed by ICP-MS using a Thermo

163 Scientific XSERIES 2 spectrometer. Recovered solutions were diluted 3 times with 2% HNO_3

164 solution to a volume of 6 mL. Finally, 0.5 mL of an In solution was systematically added as an

165 internal standard to correct for the drift of the ICP-MS. Collision Cell Technology (CCT) was

166 used for some elements (Ca, Fe, and Mn) in order to reduce polyatomic interferences with 5% H_2

167 in He gas. Measurements quality was evaluated by duplicating the measurement of standards that

168 were analysed five times on the ICP-MS. Calculations, to extract concentrations from the

169 integration of peak signals, were performed off-line. Reproducibility depends on the nature of the

170 analysed element. It ranges between 1 and 19% for the REE and from 3 to 30% for other trace

171 elements. The detection's limits (D.L.) are defined as 3 times the blanks average. All data below

172 the detection limit were excluded. Because the torch for ICP-MS was sheathed in quartz, Si was

173 then determined by atomic emission spectrometry (ICP-AES) using a Perkin Elmer Optima 3000

174 DV ICP-AES. Solutions were diluted five times using a 2% HNO_3 solution providing the

175   minimum analysable volume. The same HNO_3 solution was used to prepare standards and blanks.

176   The analytical error for Si is 8 %.

177

178   **2.4.2 Capillary electrophoresis (CE)**

179   The anionic content (Cl^-, SO_4^{2-}, F^-, PO_4^{3-}, HCO_3^-) in the recovered solutions was quantified

180   using a capillary electrophoresis (CE) system by WATERS®. The CE apparatus was equipped

181   with a fuse capillary (75 µm i.d. x̶×̲ 60 cm total length) and a diode detector. The CE was operated

182   at 20 °C and at a voltage of 20 kV. Electrophoregrams were recorded with the indirect mode

183   detection at 254 nm using an Hg lamp. The background electrolyte (BGE) was composed of 4.6

184   mmol/L Na_2CrO_4 solution, 0.5 mmol/L OFMOH™ from WATERS™, and an H_3BO_4 solution (pH

185   = 8.0). Prior to each measurement series, the capillary was conditioned by flushing with 1 mol/L

186   NaOH and 0.1 mol/L NaOH (5 min each) followed by a 10 min flush with deionized water and a

187   BGE solution (15 min flush). The capillary was preconditioned prior to each measurement by

188   flushing the BGE for 1 min. All samples were measured in duplicate using hydrostatic injection

189   mode.

3 Results

3.1 Allanite alteration as a function of the initial pH

The role of initial pH was investigated by time-series experiments in order to evaluate, together with the final alteration extent, the kinetics of the reaction. The experiments were performed for F-doped system at a duration of between 15 and 180 days under initial acidic and high pH alkaline conditions (Table 1).

The recovered experimental solids, characterized by X-ray diffraction, displayed alteration evidence with secondary phases in the run products (Fig 1). The extent of alteration was estimated on the basis of remaining allanite in the recovered samples. The constancy of the allanite composition between the final and initial materials (Table S1 - Supp. Mat) attested to no secondary allanite/epidote precipitation. The reaction progress was estimated from the allanite abundance. The run products modal composition showed that the kinetics and extent of alteration greatly varied with the initial pH (Fig. 1). The alteration rate was much higher in the high pH alkaline system, with 65% alteration reached within the first 15 days and a rapid stabilisation at around 70 to 75% alteration from 30 to 120 days. In contrast, the extent of alteration in the acidic experiments was scarce after 15 days and only achieved 25% alteration for the longest durations (120 and 180 days). However, under both the acidic and high pH alkaline conditions, with a F-doped solution, the same mineral phases grew at the expense of allanite (Fig. 1): analcime (Na-Al silicate), hematite (Fe_2O_3), and REE-bearing carbonates (Table 2). The REE-bearing carbonates, determined from XRD analyses, changed depending on the initial pH of the solution. They consisted of (1) bastnäsite (general formula: $LREECO_3F$) and synchysite (general formula:

11

211 CaLREE$(CO_3)_2$F) under acidic conditions and (2) a burbankite-group mineral (thereafter referred

212 as BGM, with the general formula: (Na,Ca)$_3$(Sr,Ba,Ce)$_3$(CO$_3$)$_5$) and REE-fluorocarbonates with

213 parisite (general formula: CaLREE$_2$(CO$_3$)$_2$F$_2$) associated with bastnäsite and minor synchysite in

214 the high pH alkaline system. Besides these phases, fluorite (CaF$_2$) appeared in the acidic

215 experiments, while calcite (CaCO$_3$), smectite, and minor nordstrandite (general formula:

216 Al(OH)$_3$) crystallized in the high pH alkaline system. High REE contents up to 2 wt% and 8 wt%

217 (REE+Y)$_2$O$_3$were measured in fluorite and calcite, respectively (Table 2; Table S2 supp. mat.).

218 　　　The microstructures of the recovered solids differed depending on the initial pH, which

219 can be attributed to the reaction progress. In acidic system, due to low alteration rate (15 days),

220 the initial shape of the allanite grains, characterized by typical conchoidal edges, was mostly

221 preserved while fluorite and analcime crystals grew around allanite from the bulk fluid (Fig. 2a).

222 The allanite surface was pitted, however, and covered by smectite in a typical honeycomb

223 structure (Fig. 4b). At this stage, REE-(fluoro)carbonates were restricted to inherited fractures in

224 the allanite. A higher reaction extent (25%) in the acidic system (120 days), resulted in alteration

225 rims surrounding some of the allanite grains. Their surfaces were characterized by a pervasive

226 saw-tooth shaped reaction front, highlighting more extensive dissolution (Fig. 2b). Reaction rims

227 were sequentially composed of discontinuous layers of hematite followed by nanocrystals with

228 the granular and acicular shape of REE-fluorocarbonates penetrating through the dissolving

229 allanite at the reaction front and filling newly-opened fractures (Fig. 2c).

230 　　　In the high pH alkaline run products, the allanite grain shape is preserved on the micro-

231 scale, surrounded by layers of complex micro-textures. The morphologies and textures described

232 for the run product from the 15-days experiment do not significantly change compared to the

233   longer duration experiments. Allanite has penetrative reaction rims that can reach up to 10 μm

234   thick (Fig. 2d). They were delimited by complex microstructures at the reaction front, such as

235   nanoscale etch pits or saw-tooth surfaces (Fig. 2e). Close to the reaction front, REE-

236   fluorocarbonates also precipitated at the surface, within the etch pits or in inherited microfractures,

237   with nano-granular, acicular, or prismatic shapes (Fig. 2e). The sub micron size of these phases

238   prevented quantitative chemical analyses by EMPA. The allanite surface was overlain with a thin

239   layer of hematite crystals of around 10 to 500 nm in size. Smectites were also ubiquitous and

240   clearly identifiable by their fibrous (honeycomb) morphology and platelet growth oriented

241   towards the fluid. The burbankite-group minerals (BGM) occur as microscale euhedral crystals

242   that randomly precipitated from the reactive bulk fluid (decoupled from the allanite replacement

243   products). They are mainly prismatic and more or less elongated with a size generally varying

244   from ca. 5 to 30 μm in size (Fig. 2f). The BGM crystals commonly display a zonation with respect

245   to the REE content which is anti-correlated with respect to Ca (Fig. S5, supp. mat.). They have a

246   higher LREE than the initial allanite, but with Sm and Y below the detection limit (Table 2).

247   Calcite precipitates as aggregates of euhedral crystals 10 to 20 microns in size or intergrown with

248   relic allanite (Fig. 2f).

249   **3.2 Allanite alteration as a function of ligands**

250   To investigate the effects of ligands on the alteration of allanite, experiments were run under the

251   initial acidic conditions with P-doped, S-doped and Cl-doped solutions for 120 days (Table 1).

252   Similar to that observed for the pH, the reaction progress was also significantly affected by the

253   ligands (Fig. 3). The most reactive system was the P-doped one, which achieved 73% allanite

254   alteration. This reaction extent was similar to that seen in the F-doped system under high pH

13

255 alkaline conditions (75~~%),~~% of reaction), but much higher than that obtained under similar acidic

256 conditions (23~~%,~~% of reaction) over the same duration (120 days). The S- and Cl-bearing systems

257 were ~~not~~less reactive compared to the others with less than 5% secondary minerals.

258 In the reactive P-doped experiments, analcime and hematite were present in major proportions in

259 the recovered solid, as for the F-doped system. Smectite was also an alteration product of allanite,

260 as in the high pH alkaline system. The main difference between the P- and F-doped systems was

261 the nature of the mineral phases that accommodated REE and Ca, such as monazite (general

262 formula LREEPO$_4$, 21% of solid product) and hydroxyapatite (general formula Ca$_5$(PO$_4$)$_3$OH,

263 18% of solid product). The alteration microstructures were very similar to those previously

264 described in the F-bearing system. Allanite was largely affected by dissolution, as illustrated by

265 the numerous etch pits scattered on the allanite surface (Fig. 4a). Allanite alteration resulted in

266 thick reaction rims made up of a nano-mixture of monazite-hematite and hydroxylapatite with an

267 apparent microscale spatial distribution from the reaction front towards the reactive fluid (Fig 4b).

268 Sub-micron monazite crystals precipitated directly at the interface with the allanite (Fig. 4c).

269 Similar to the F-doped systems, hematite occurred as a thin, quasi-continuous corona around the

270 allanite grains. Finally, euhedral micrometric-sized grains of hydroxylapatite, mixed with smectite

271 filaments, which probably formed during the quench, are seen along the outer edge of the

272 alteration rim (Fig. 4b and c). Analcime remains the major alteration phase, and takes the form of

273 large grains embedding relict allanite along the allanite reaction rims (Fig. 4a).

274

3.3 Recovered fluid chemistry

Beside solid product characterization, the fluid composition was also analysed for each experiment (Table 3; Fig. 5). While the fluid compositions can be modified by internal and external factors through the course of the reaction (water consumption by alteration products, permeability limits of the Teflon reactors, quenching effects), the reproducibility of the results supports the general qualitative significance of the fluid chemistry dataset.

In time-series experiments, the ~~final~~ fluid compositions indicated that the experiments under high pH alkaline conditions were already in a steady-state (approaching constant concentrations of all measured elements with time) after 15 days (Fig. 5b), which is in agreement with the mineralogical results. In the initially ~~acid~~acidic system, elemental concentrations of Ca, REE, Th~~,~~ and U evolved until reaching a near plateau only after 120 days (Fig. 5a). At that stage, Si, Al, and Ca reached similar concentrations in the F-doped acidic and high pH alkaline systems, whereas REE, U~~, and~~ Th were lower in the acidic system compared to the high pH alkaline system by 2 to 4 orders of magnitude.

In the P-doped system, which was the most reactive system under acidic conditions, elemental concentrations are similar to the concentrations of the F-doped in the acidic system at 120 days (Fig. 5c). In the unreactive Cl- and S-doped systems, Si and REE concentrations are comparable with those measured in the F- and P-doped systems under acidic conditions. The other elements were generally at lower concentrations.

In terms of REE, the chondrite-normalized patterns plot relatively flat for the high pH alkaline systems (Fig. 6). ~~There is~~In acidic fluids, patterns plot also relatively flat but with a

15

296 ~~MREE~~slight depletion ~~compared to LREE~~in Sm, Gd and ~~HREE in acidic fluids~~Dy, with no

297 dependence on the ligand.

298

4. Discussion

4.1 Allanite alteration mechanisms

301   In the batch experiment runs (Table 1), the alteration of allanite ranges from a very limited

302 (< 5%) up to a very extensive (77%) degree depending on the fluid chemistry after 120 days. The

303 pH has the first effect on the alteration of allanite, as the kinetics for the high pH alkaline system

304 are fastest (65%) after 15 days, and the more advanced (70–75%) after 120 days in the two time-

305 series experiment runs conducted in an F-doped system. Under acidic conditions, the nature of

306 the ligand significantly affects the extent of alteration. The presence of P enhances the allanite

307 alterability, reaching 73% of the reaction rate after 120 days, while allanite reactivity is minor in

308 the Cl- or S-doped systems (< 5%). F-doped systems display moderate alteration at the same

309 duration (25%). Higher allanite reactivity in a high pH alkaline fluid shows that high pH fluids

310 efficiently promote silicate dissolution rates, while dissolution is more limited in near neutral

311 fluids (Hellmann, 1994). This effect is also demonstrated for epidote group minerals (Rose, 1991).

312 Phosphorus seems to have a similar effect on allanite, though with a lower extent of alteration.

313 In the most reactive systems (high pH alkaline and P-doped conditions), the alteration of allanite

314 is promoted by increasing dissolution coupled with the precipitation of other minerals. On one

315 hand, dissolution can be promoted due to a solubility change for the dissolving elements in the

316 bulk solution, by modifying element complexation, the concentration in the solution, and the

317 chemical affinity per the dissolution reaction between allanite and the fluid. On the other hand,

318 the mineral microstructures evidenced here also point to the crucial role of secondary precipitation

319 on the alteration rate. Alteration microstructures from highly altered ~~run~~experiment products show

320 well-developed dissolution features (etch pits, fractures, porosity) with a penetrative replacement

321 by an alteration rim made up of secondary minerals with a complex mineralogical zonation.

322 General preservation of the initial pristine shape of allanite suggests a mechanism of replacement

323 by interfacially coupled dissolution-precipitation (Putnis, 2002; Putnis and Putnis, 2007;

324 Hellmann et al., 2012), which indicate disequilibrium between the solid and the fluid (Putnis,

325 2009; Ruiz-Agudo et al., 2014). Such alteration processes can lead to an apparent incongruent

326 dissolution due to a preferential precipitation of low solubility phases (with different composition

327 than the altered phase) at the alteration interface (Ruiz-Agudo et al., 2012). Such apparent

328 incongruent dissolution has already been demonstrated for epidote dissolution (Kalinowski et al.,

329 1998), and seems also to apply here to allanite alteration as seen by the mineralogical gradation

330 from the reaction front to the bulk solution. In the reaction rim, the precipitation of submicron,

331 low-solubility secondary phases takes in elements from the solution and changes their

332 concentration at the reaction interface. This is the case for hematite, which nucleates as a thin rim

333 at the interface with the allanite. But this is particularly true for REE-mineral phases, (REE-

334 fluorocarbonates or monazite depending on the ligand), which also occur as a discontinuous rim

335 of nano-scale crystallites propagating anisotropically inward into the pristine grain and along

336 fractures in the allanite. The growth of other main phases with a higher solubility in the solution,

337 e.g. analcime, fluorite, and calcite, is spatially decoupled from the alteration interface with

338 precipitation from the bulk solution as larger euhedral crystals. Such precipitation from the bulk

339 fluid away from the rim of the dissolving mineral have been described in other alkaline systems

17

340 (Lafay et al., 2014, 2018). In the batch experiment runs, the preferential precipitation of REE-

341 phases at the reaction front is proposed to efficiently maintain significant dissolution rates by

342 producing steep concentrations gradients in the fluids close to the reactive surface, which act to

343 renew the solutions (Ruiz-Agudo et al., 2016; Frugier et al., 2008).

344 Coupled with the chemical gradient at the interface, the precipitation of REE-mineral phases will

345 further strongly modify the geometry of the reaction front. The complex microstructures at the

346 reaction interface, with etch pits, indentations, and secondary fractures, are the result of reaction-

347 induced fracturing due to molar volume change and the force of crystallization during the

348 replacement of allanite by secondary phases (e.g. Jamtveit et al., 2009; Lafay et al., 2018). This

349 increase of the reactive surface also enhances allanite dissolution.

350   In the two non-reactive systems (Cl- and S-doped), there was very limited precipitation

351 of secondary phases (< 5%). In batch experiment runs, this drop in the dissolution rates can occur

352 when element concentrations progressively approach saturation in the fluid or when precipitation

353 of an inert passivation layer isolates the reacting mineral from the reactive fluid (Montes-

354 Hernandez et al., 2012). In unreactive systems, secondary precipitation observed at the grain

355 surface is sufficiently low such that allanite remains accessible to the fluid throughout the

356 experiment runs. In contrast, concentrations in fluids similar to those of reactive systems indicate

357 that they reach conditions approaching saturation. Since precipitation of analcime and hematite is

358 not chemically restricted, the only limiting factor here appears to concern the stability of the REE-

359 phases.

360   In the investigated reactive systems, the ~~precipitated~~precipitation of secondary REE-

361 phases is thus proposed to be the main driving force behind allanite alteration by lowering the

18

362 activities of REE in the interfacial fluid. In the absence of efficient REE-mineral precipitation (Cl-

363 and S-doped) at the allanite interface, "steady state" concentrations measured in the bulk fluid are

364 assumed to be more readily reached, thus decreasing reaction rates. Therefore, allanite alteration

365 remains low. These results are in good agreement with natural observations. The secondary,

366 experimental REE-mineral phases, i.e., REE-fluorocarbonates and/or REE-phosphates ~~associated~~

367 ~~with~~are typical of low-temperature alteration products (e.g. Berger et al., 2008; Ondrejka et al.,

368 2018).

369

4.2 REE, Th, and U mobility and fractionation during allanite alteration

371 In all reactive systems, comparison between a simple mass balance calculation from the

372 low REE concentrations in the recovered fluid and the allanite composition and alteration rates

373 ~~indicate~~indicates that the REE released during alteration are mostly in secondary phases. Seventy

374 percent allanite alteration would provide 100 µmol of the REE released in high pH alkaline

375 experiment runs. However, the REE contents in the final fluids are 4 orders of magnitude below.

376 The main REE-minerals (REE-carbonates or REE-phosphates identified by XRD), occur as

377 submicronic crystals in the alteration rim, preventing accurate determination of their REE

378 contents. Based on the theoretical compositions of REE-fluorocarbonates and monazite, along

379 with their XRD modal abundance, rough mass balance calculations confirm that they are a major

380 sink for the REE released by allanite. In the P-doped system, the hydroxylapatite grains are also

381 too small for determining their REE content though it could be up to a few wt.% (Budzyń et al.,

382 2017).

383   While the composition of secondary phases in the altered rim cannot be analysed precisely

384   for their REE ~~compositions~~contents, minerals precipitating from the bulk-fluid are large enough

385   for evaluating their REE content by EPMA. In F-doped systems, fluorite represents 25% of the

386   secondary products, and can incorporate up to 1-2 wt.% ~~REE~~REE_2O_3. The REE content in fluorite

387   has been extensively studied in hydrothermal systems (Möller et al., 1998; Schwinn and Markl,

388   2005; Schönenberger et al., 2008; Gob et al., 2011), in economical REE-deposits, such as the

389   Bayan Obo complex (Xu et al., 2012), or by thermodynamic modelling (Kolonin and Shironosova,

390   2007). It shows that REE in fluorite, while extremely variable, but can reach up to > 10 wt.% in

391   yttrofluorite (Pekov et al., 2009). Although a coupled substitution involving Na is often considered

392   preponderant for incorporating the REE ~~within~~in fluorite, i.e. $REE^{3+} + Na^+ \leftrightarrow 2\ Ca^{2+}$ (Möller et

393   al., 1998), there is no real correlation between the REE and Na contents in the fluorite from these

394   experiments, despite the high Na concentrations. The BGM (identified from XRD) precipitating

395   from the bulk-fluid also accommodate significant REE, but with Na concentrations that are ~~too~~

396   ~~low~~significantly lower compared to burbankite *sensu stricto* (Beloviskaya and Pekov, 2004). The

397   BGM are zoned with a typical hourglass sector zoning suggesting crystallographic control on REE

398   incorporation (Fig. 2f). Integration of the REE is directly correlated to the size and geometry of

399   the crystallographic sites, which favour the LREE in calcic minerals, such as tourmaline (van

400   Hinsberg et al., 2010). Burbankite is a hydrothermal mineral encountered in alkaline pegmatites

401   and associated carbonatites (Zaitsev et al., 2002). In the experiments, the precipitation of BGM

402   minerals is probably favoured by the Na concentration in the fluid. Finally, the REE

403   concentrations in the calcite are considerably higher than those normally encountered in nature

404   (Stipp et al., 2006) but are thermodynamically stable (Rimstidt et al., 1998) as has been

405   experimentally demonstrated (Toyama and Terakado, 2014; Gabitov et al., 2017). In calcite, two

406 coupled substitution mechanisms are proposed as follow (Perry and Gysi, 2018), i.e. $REE^{3+} + Na^+$

407 $\leftrightarrow 2Ca^{2+}$ and $2REE^{3+} + \square \leftrightarrow 3Ca^{2+}$. The composition of the calcite produced in these experiments

408 ~~indicate~~indicates that both mechanisms occur under the experimental conditions of this study (Fig.

409 S5, supp. mat.).

410

4.3 REE fractionation between fluid and solid

412   Though the REE are mainly stored in secondary phases, minor REE concentrations have

413 been recovered in the fluids. Though precise quantitative fluid concentrations are limited by the

414 batch experimental setup, our qualitative results clearly indicate a significant difference in REE

415 fractionation between the solid and the fluid whatever the pH and the complexing ligands.

416 Experimental fluids display relatively flat chondrite normalized REE spectra, indicating that the

417 experimental alteration of allanite ultimately produces a fluid enriched in HREE relative to the

418 initial LREE-rich allanite composition. This implies in turn the preferential fractionation of LREE

419 over HREE in the secondary mineral precipitates relative to the fluid. This is in good agreement

420 with the limited incorporation of HREE in fluorocarbonates and monazite, as demonstrated for T

421 < 450 °C (Heinrich et al., 1997; Poitrasson et al., 2000; Janots et al., 2008; Budzyń et al., 2010;

422 2017; Grand'Homme et al., 2018). Also, secondary minerals that precipitate from the bulk-fluid

423 (calcite, fluorite, BGM) are enriched in LREE over HREE but with lower La/Y compared to

424 allanite, again supporting the fractionation of the LREE over the HREE in the bulk fluid compared

425 to fluid at the reaction front. In these secondary mineral phases, the Y values are typically at the

426 same level as in allanite, which suggests that the HREE are more mobile compared to the LREE,

427 as seen in numerous natural environments, e.g. during monazite alteration (Hentschel et al., 2020).

428 The fluid compositions measured in this study have numerous implications for REE

429 deposits. Here the flat or gently incurved REE normalized pattern indicates that REE are not

430 released congruently but that speciation in the fluids or precipitation of secondary products favour

431 HREE fractionation over LREE in the fluid compared to the initial allanite composition.

432

4.4 Th and U behaviour during allanite alteration

434 Actinides seem to mostly partition into the fluid as opposed to secondary minerals.

435 Simplified qualitative calculations show that virtually all the U released by allanite goes into the

436 fluid under these conditions. Actinide concentrations are higher in the high pH alkaline system

437 (with higher carbonate activities) than in the acidic system. This agrees rather well with studies

438 that show that the solubility of actinides increases with the concentration of the aqueous carbonate

439 or phosphate ligands (Rai et al., 1994; Sandino and Bruno, 1998). Recent studies also show that

440 actinides can be highly mobile in the presence of ligands such as S-, Cl-, or F-complexes for

441 temperatures close to 200 °C (Nisbet et al., 2018, 2019; Migdisov et al., 2019). In the experimental

442 runs under initial acidic conditions, U release is however at least 1 to 2 orders of magnitude lower

443 than that under high pH alkaline conditions. Regardless of the chemical system, Th is

444 systematically lower in the fluid compared to U while it is higher in the starting allanite, indicating

445 U/Th fractionation during allanite alteration. According to Rai et al. (1994), ThO_2 solubility is

446 higher than that of UO_2, suggesting that tetravalent U is likely oxidized in its hexavalent state

447 during the allanite alteration reaction. Preferential incorporation of tetravalent Th in secondary

448 REE-mineral phases may in turn enhance Th/U fractionation between the fluid and secondary

449 products as observed in natural monazite and allanite precipitated from hydrothermal systems

450 (Janots et al., 2012).

451

5. Conclusions

453 Allanite has a complex composition and its experimental alteration under low temperature

454 conditions results in a high diversity of mineralogical assemblages and microstructures. Allanite

455 can be highly reactive in certain fluids, reaching more than 75% of alteration at 200 °C and $P_{sat} \approx$

456 16 bar, after only 15 days. The pH and the nature of the complexing ligand added to the fluid will

457 strongly affect the alteration rate of the allanite, with the high pH alkaline system being the most

458 reactive. In carbonate-bearing fluids, F and P will promote allanite alteration, while allanite shows

459 negligible alteration in the presence of Cl and S. The main driving force behind the alteration of

460 allanite resides in the precipitation at a reactive front of secondary REE-minerals, whose

461 chemistry depends on the complexing ligands. These precipitated minerals maintain a local

462 disequilibrium close to the reaction interface between the fluid and the solid, thus sustaining

463 allanite dissolution. Though REE are mostly stored in the secondary mineral phases, there is a

464 preferential fractionation of the LREE over the HREE into the solid compared to the fluid while

465 U is strongly partitioned into the fluid.

Figure Captions

Figure 1. Evolution of the proportion of the starting material and run products, utilizing Rietveld refinement (in %) for initial acidic (**a**) and high pH alkaline (**b**) F-doped systems. The group of REE-carb represents bastnäsite + synchysite in acidic system, and parisite + bastnäsite + synchysite + the burbankite-groupe mineral in the high pH alkaline system. These REE-carbonate minerals were identified by XRD analyses. Full lines represent the maximum allanite replacement in a state close to equilibrium. Numerical values are presented in Table 1. Aln = allanite; Ana = analcime; Cal = calcite; Fl = fluorite; Hem = hematite; Nrd = nordstrandite; Sme = smectite.

Figure 2. Scanning electron microscopy images using backscattered electron (BSE) imaging of allanite and secondary products from acidic (a, b, and c) and high pH alkaline (d, e, and f) F-doped runs for different times. **a.** Relatively unaltered allanite with fluorite and analcime growing along the allanite grain rims. **b.** Relatively unaltered allanite (top left) with internal fractures filled by REE-phases along with more reacted allanite (bottom right) with sawtooth-shaped grain rims after 120 days. **c.** Magnification of b showing reaction interface with allanite composed of granular nanometric REE-fluorocarbonates replacing allanite. **d**. Allanite grain displaying edge pitting with a porosity that progresses anisotropically to the grain center. Edges are rimmed by a saponite whiskers, which probably formed during quenching. **e**. Detail of an allanite edge showing a sharp eroded surface rimmed by REE-fluorocarbonates with a granular, prismatic, and needle-like shape, along with hematite and saponite. Porous cavities are filled with REE fluorocarbonates **f.** Cluster of Burbankite-group minerals with a large crystal of calcite growing in the interstitial space between the minerals. Aln = allanite; Ana = analcime; Bgm = burbankite-group mineral; Cal = calcite; Fl = fluorite; Hem = hematite; REE-FCb = REE-fluorocarbonates (bastnäsite, parisite, synchysite); Sap = saponite; Sme = smectite.

Figure 3. Comparison of mineral modal compositions after 120 days for the F-doped high pH alkaline systems and the F-, P-, S-, and Cl-doped systems (respectively shown in columns), which

32

were identified by X-ray diffraction (XRD) and Rietveld refinement (in %). Aln = allanite; Ana = analcime; Anh = anhydrite; Cal = calcite; Fl = fluorite; Hal = halite; Hap = hydroxylapatite; Hem = hematite; Mnz = monazite; Nrd = nordstrandite; Sme = smectite.

Figure 4. Secondary electron (SE) and backscattered electron (BSE) images of allanite alteration in an acidic P-doped system. **a**. Typical allanite grain with eroded grain boundaries and with large crystals of analcime partially embedding the other secondary minerals. **b**. Continuous reaction front composed of monazite replacing allanite and a thin (< 200 nm) rim of hematite outlining the original shape of the allanite. Outwards from the reaction front is rimmed by euhedral hydroxyapatite (Hap) that precipitated in the interstitial space between filaments of saponite (Sap). **c**. Detail from **b** showing that the abundance of the nano-size monazite increases in the vicinity of the eroded allanite. Aln = allanite; Ana = analcime; Cal = calcite; Hap = hydroxylapatite; Hem = hematite Mnz = monazite; Sap = saponite.

Figure 5. Major elements, REE, and actinide concentrations (log) in experimental fluids for the time series F-doped experiments in the acidic system (**a**), high pH alkaline system (**b**), and in the 120 day experiments for the P-, S-, and Cl-doped systems (**c**).

Figure 6. Chondrite-normalized REE spectra of fluids after 120 days from the slightly acidic, F-doped, P- doped, S- doped, Cl-doped, and time series, high pH alkaline, F-doped experiments. The HREE with odd numbers are below the detection limits or have been removed from the diagram because of artificial anomalies due to being close to the detection limits (Table 1). The lanthanide tetrad effect is discernible within the LREE for the slightly acid experiments (dashed lines).

Table 1. Experimental conditions and solid products

Set	Exp.	Carbonate source	Initial pH	Ligands (120 mM)	Duration (days)	Aln (%)	Secondary solid products
B1	B1015	Carbonic ice[1]	4	NaF	15	93	Bsn (1.2%); Syn (1.5%); Flr (2.0%); Hem (2.1%);
	B1030	Carbonic ice[1]	4	NaF	30	92	Bsn (2.2%); Syn (1.0%); Flr (2.5%); Hem (2.0%);

	B1180	Carbonic ice[1]	4	NaF	180	77	Bsn (5.6%); Flr (5.8%); Hem (4.7%); Ana (7.3%);
B2	B2015	$NaHCO_3^-$ 1M 1.5mL	8.7	NaF	15	36	Bsn (2.0%); Syn (1.0%); Pst (6.6%); BGM (8.9%); Cal (4.5%); Hem (8.9%); Ana (22%); Sme (6.7%); Nsd (3.1%)
	B2030	$NaHCO_3^-$ 1M 1.5mL	8.7	NaF	30	29	Bsn (3.1%); Syn (1.0%); Pst (8.9%); BGM (5.7%); Cal (4.5%); Hem (8.4%); Ana (26%); Sme (7.7%); Nsd (4.1%)
	B2060	$NaHCO_3^-$ 1M 1.5mL	8.7	NaF	60	31	Bsn (3.1%); Syn (1.7%); Pst (8.9%); BGM (9.4%); Cal (8.4%); Hem (9.1%); Ana (24%); Sme (7.6%); Nsd (1.8%)
	B2120	$NaHCO_3^-$ 1M 1.5mL	8.7	NaF	120	23	Bsn (5.2%); Syn (<1%); Pst (3.3%); BGM (5.9%); Cal (9.5%); Hem (9.9%); Ana (31%); Sme (7.2%); Nsd (3.8%)
B3	B3P120	Carbonic ice[1]	4	$Na_3PO_4.12H_2O$	120	27	Mnz (15%); Hap (13%); Hem (6.8%); Ana (31%); Sme (6.3%)
	B3S120	Carbonic ice[1]	4	Na_2SO_4	120	97	Anh (1.6%); Ana (1.6%)
	B3Cl120	Carbonic ice[1]	4	NaCl	120	98	Hl (2.0%)

Carbonic ice is certified 100% pure CO_2 – around 30 mg (after the epoxy reactor closure). Estimated standard deviation is < 2% for values > 10% and does not exceed 10% for lower quantification. Aln = allanite; Ana = analcime; Anh = anhydrite; BGM = burbankite-group mineral; Bsn = bastnäsite; Cal = calcite; Chl = chlorite; Flr = fluorite; Hap = hydroxyapatite; Hem = hematite; Hl = halite; Mnz = monazite; Nsd = nordstrandite; Pst = parisite; Sme = smectite; Syn = synchysite. For a better reading comprehension with Aln (allanite), Ana designate analcime instead of the common abbreviation Anl. Abbreviation from Warr L.N. (2021) IMA–CNMNC approved mineral symbols. Mineralogical Magazine 85, 291–320.

**Table 2**. Microprobe selected analyses of major run products (wt%).
