## ABSTRACT

Manganese(IV) oxides, and more especially birnessite, rank among the most efficient metal oxides for As(III) oxidation and subsequent sorption, and thus for arsenic immobilization. Efficiency is limited however by the precipitation of low valence Mn (hydr)oxides at the birnessite surface that leads to its passivation. The present work investigates experimentally the influence of chelating agents on this oxidative process. Specifically, the influence of sodium pyrophosphate (PP), an efficient Mn(III) chelating agent, on As(III) oxidation by birnessite was investigated using batch experiments and different arsenic concentrations at circum-neutral pH. In the absence of PP, Mn(II/III) species are continuously generated during As(III) oxidation and adsorbed to the mineral surface. Field emission-scanning electron microscopy, synchrotron-based X-ray diffraction and Fourier transform infrared spectroscopy indicate that manganese is formed, passivating birnessite surface and thus hampering the oxidative process. In the presence of PP, generated Mn(II/III) species form soluble complexes, thus inhibiting surface passivation and promoting As(III) conversion to As(V) with PP. Enhancement of As(III) oxidation by Mn oxides strongly depends on the affinity of the chelating agent for Mn(III) and from the induced stability of Mn(III) complexes. Compared to PP, the positive influence of oxalate, for example, on the oxidative process is more limited. The present study thus provides new insights into the possible optimization of arsenic removal from water using Mn oxides, and on the possible environmental control of arsenic contamination by these ubiquitous nontoxic mineral species.

## 1. Introduction

In natural waters, arsenite, As(III), mainly occurs as the neutral species  $\text{H}_3\text{AsO}_3$ , while arsenate, As(V), is present as  $\text{H}_2\text{AsO}_4^-$  or  $\text{HAsO}_4^{2-}$  oxyanions under a variety of pH conditions (Cerkez et al., 2015). Both forms are highly toxic and carcinogenic, and the maximum contaminant level for arsenic in drinking water defined by the World Health Organization (WHO) is thus extremely low at 10  $\mu\text{g}/\text{L}$ . Arsenite is even more toxic and mobile than arsenate in aqueous environments (Cerkez et al., 2015; Fischel et al., 2015; Neppolian et al., 2010) and more difficult to remove owing to its low affinity for sorbents (Luong et al., 2018). Oxidizing As(III) into the more easily extractable As(V) thus appears appropriate to

achieve efficient arsenic immobilization and removal (Zhang et al., 2016).

Although As(III) is stable in homogeneous systems (Katsoyiannis and Zouboulis, 2004; Tsang et al., 2007), a variety of metal oxides such as iron (hydr)oxides (Amirbahman et al., 2006; Wang and Giammar, 2015; Yang et al., 2017; Zhao et al., 2011) and titanium oxides (Dutta et al., 2004; Ferguson et al., 2005; Guan et al., 2012) can induce its oxidation directly or indirectly. As a consequence, As concentration in natural aqueous environments is essentially controlled by interactions with mineral surfaces. Composite oxides have also been developed to enhance their efficiency as oxidants and adsorbents for both As(III) and As(V) (Chakravarty et al., 2002; Feng et al., 2006a; Ma et al., 2020; McCann et al., 2018; Wu et al., 2018; Ying et al., 2012; Zhang et al., 2007, 2018; Zheng et al., 2020). Manganese (Mn) oxides can also oxidize As(III) (Manning et al., 2002; Scott and Morgan, 1995), as

reported in natural lacustrine environments (Oscarson et al., 1980, 1981a, 1981b), and Mn oxides have a key role in As geochemical cycling (Driehaus et al., 1995; Nesbitt et al., 1998; Scott and Morgan, 1995; Tournassat et al., 2002). Produced Mn(II) adsorbs to the particle edges, thus potentially blocking reactive sites for further oxidation (Villalobos et al., 2014). Lafferty and coworkers (Lafferty et al., 2010a, 2010b, 2011) identified Mn(II) as the unique reduced product during the initial phase of the reaction. They also concluded that Mn(III) was subsequently formed as the result of the comproportionation of Mn(II) adsorbed onto birnessite surface rather than from Mn(IV) reduction, as previously hypothesized (Nesbitt et al., 1998). Manganite ( $\gamma$ -Mn(III)OOH) then accumulates at the birnessite surface leading to its passivation, as Mn(III) sites are less reactive than Mn(IV) ones with respect to As(III) oxidation, as shown by DFT calculations (Zhu et al., 2009). Finally, Lafferty and coworkers showed that As(V) was the sole As species adsorbed to manganese oxides (Lafferty et al., 2010a, 2010b, 2011).

In contrast to the optimization of the oxidizing solid, little attention has been paid to the influence of additional chemicals present in the reactive medium. For example, the presence of phosphate in solution hampers As(III) oxidation by Mn oxides (Chiu and Hering, 2000; Parikh et al., 2010), whereas that of tartaric acid promotes it (Feng et al., 2006b). More generally, the presence in the reactive medium of compounds chelating Mn, and more especially Mn(III), is expected to enhance the oxidative process (Ma et al., 2020). With this respect, pyrophosphate (PP) appears especially relevant owing to its strong affinity for Mn(III) (Liu et al., 2019; Marafatto et al., 2018; Parker et al., 2004; Soldatova et al., 2017). The relevance of PP is further increased by its common formation in natural environments, as the simplest polymer of orthophosphate resulting from the breakdown of ATP and ADP (Klewicki and Morgan, 1999; Trouwborst et al., 2006).

The present experimental work thus investigated in detail the influence of PP on As(III) oxidation by the Mn oxide birnessite at circumneutral pH. The effect of PP addition on the completeness of the reaction and the involved reaction mechanisms were specifically studied from a combination of wet chemical analyses and of solid phase characterization using electron microscopy, X-ray diffraction, X-ray absorption and photoelectron spectroscopies, and infrared spectroscopy.

## 2. Materials and methods

### 2.1. Chemicals

All chemical used in the present study were purchased from Sinopharm Chemical Reagent, except for the manganese(III) acetate dihydrate which was purchased from Sigma Chemical. All chemicals were of analytical grade. Atomic absorption spectroscopy Mn standard was prepared by dilution of a 1000 mg/L standard. Deionized water was used throughout the experiments.

### 2.2. Synthetic acid birnessite preparation

Synthetic acid birnessite was prepared according to a method modified from that of McKenzie (1971). In brief, 45 mL of a 6 M HCl solution were added dropwise to 300 mL of a boiling 0.667 M solution of  $\text{KMnO}_4$ . The obtained suspension was stored at 60°C for 12 h to increase birnessite crystallinity. Resulting solid was then washed with deionized water and centrifuged ( $10 \times$ ) to remove  $\text{K}^+$  and  $\text{Cl}^-$  in excess.

### 2.3. Batch As(III) oxidation by birnessite and wet chemical analyses

Batch experiments were conducted using 50 mL of a 0.2 g/L suspension of the obtained synthetic birnessite at two As(III) con-

centrations (0.5 and 1 mM) in the presence/absence of sodium pyrophosphate (PP). When present, PP concentrations were 1, 2, 3, 4, 5, 8, and 10 mM, with a 2.5 mM NaCl background electrolyte. Mixed suspensions, whose pH was pre-adjusted to 7.2 using 0.2–1 mM HCl, were then stirred for 24 h. The solids were subsequently filtered and washed thoroughly with deionized water to remove residual dissolved ions.

In the absence of PP, As(V) and total As concentrations were determined using the molybdenum blue method (Feng et al., 2018), the concentration of As(III) being calculated from that of total As by subtracting As(V). In the presence of PP, As(III) and As(V) were determined using coupled LC-ICP-MS, As(III) and As(V) being separated by liquid chromatography (LC – Dionex IonPac AS19 Columns, ICP-MS – PerkinElmer NexION 350X) using a four-component mobile phase (pH 10.22) at 1 mL/min flow rate. The outflow from the LC was directly connected to the inductively coupled plasma mass spectrometer (ICP-MS) for As quantification. In specific experiments, PP was replaced by other chelating agents, such as sodium oxalate. In this case, As(V) and total As concentrations were also measured using the molybdenum blue method (Feng et al., 2018).

Mn concentration in solution was determined using atomic absorption spectrometry (AAS – Agilent Technologies 200 series). In addition, concentration of Mn(III)-PP complexes were determined with a UV-Vis spectrophotometer (Agilent Technologies Cary 8454), using 10 mm path length cuvettes and the absorption peaks at 258 nm and 480 nm (Webb et al., 2005).

### 2.4. Characterization of the solid products

#### 2.4.1. Mn K-edge XANES and Mn speciation analysis

X-ray absorption near edge structure (XANES) spectroscopy data were collected at room temperature on the 1W1B beamline at the Beijing Synchrotron Radiation Facility (BSRF) over the 6.4–7.0 keV range (Mn K-edge). Energy calibration was systematically performed using a Mn metal foil before data collection. Mn K-edge spectra were averaged and background-subtracted using the following parameters:  $E_0 = 6538$  eV,  $\text{Rbkg} = 1$  Å and  $k\text{-weight} = 2$ .

#### 2.4.2. Field emission scanning electron microscopy

Gold-coated samples were observed using a field-emission scanning electron microscope (FESEM – SU8010, Hitachi) with a maximum resolution of 1 nm. For high-resolution images, the microscope was operated at 10 kV using a working distance of 10–15 mm, and an in-lens secondary electron detector.

#### 2.4.3. Synchrotron radiation X-ray powder diffraction

Synchrotron radiation X-ray powder diffraction (SR-XRD) was performed on the BL14B1 beamline of the Shanghai Synchrotron Radiation Facility (SSRF). Data were collected over the 2–45 °  $2\theta$  range ( $\lambda = 0.6895$  Å), with 30 s exposure times (Yang et al., 2015).

#### 2.4.4. Fourier transform infrared (FTIR) spectroscopy

FTIR spectra were collected using a Bruker Vertex 70 spectrometer equipped with a deuterated triglycine sulfate detector (Bruker Optics Inc., Ettlingen, Germany). Spectra were measured over the 4000–400  $\text{cm}^{-1}$  range with a 4  $\text{cm}^{-1}$  resolution in transmission mode. Thirty-two scans were collected and averaged for each sample, the data being collected, processed, and analyzed with the OPUS program.

#### 2.4.5. X-ray photoelectron spectroscopy

X-ray photoelectron spectra (XPS) were collected using a VG Multilab2000 X-ray photoelectron spectrometer with an Al K X-ray source (1486 eV) and a base pressure of  $3 \times 10^{-9}$  Torr in the analytical chamber. The scans were recorded using the large area mode. The survey scans were collected using a fixed pass

energy of 100 eV and an energy step size of 1.0 eV, whereas the narrow scans have a pass energy of 25 eV and an energy step size of 0.1 eV. Spectra were charge-corrected to C1s with a binding energy of 284.80 eV collected from the surface adventitious carbon (Wang et al., 2010) and analyzed with the Advantage software. The parameters proposed by Ilton et al. (2016) and Bang et al. (2005) for the spectral fitting of Mn3p and As3d multiple peaks were used.

### 3. Results and discussion

#### 3.1. The oxidation of As(III) by birnessite with/without chelating agents

Based on their relative redox potentials, As(III) could be oxidized by dissolved oxygen under circum-neutral conditions ( $\Delta E$  for  $O_2/H_2O$  and As(V)/As(III) couples is 0.70 V at neutral pH). However, As(III) is mostly hydrophilic and present as neutral species below pH 9, and the kinetics of its oxidation by  $O_2$  is very slow at neutral pH (Lan et al., 2018). Consistently, the control experiments performed in the absence of manganese oxides showed that As(III) was essentially stable over a 24 h period (Fig. S1).

In the absence of PP and under similar circum-neutral conditions, birnessite was able to oxidize ~ 35% of the As(III) initially present (1 mM) to As(V) after 24 h (Fig. 1a), whereas ~10% of As adsorbed/precipitated at the birnessite surface. The As(III) concentration dropped exponentially with time over the first 2 h. The application of a pseudo-first order model yielded an apparent As(III) oxidation rate constant ( $k$ ) of  $0.1804 \pm 0.0349 \text{ h}^{-1}$  ( $k_1$ ) over this 2 h interval (Fig. 1b). The reaction slowed down over the subsequent 10 h with an apparent rate constant decreased by about one order of magnitude ( $k_2 = 0.0187 \pm 0.0015 \text{ h}^{-1}$ ), most likely as the result of the formation of a Mn precipitate passivating birnessite surface (Lafferty et al., 2010a). After 12 h, As(III) was not oxidized by birnessite anymore, consistent with the following equations proposed for As(III) oxidation (Lafferty et al., 2010a, 2010b):

According to these equations, As(III) oxidation occurs as a two-electron transfer process, the formation of Mn(III) resulting from the comproportionation of surface-adsorbed Mn(II) and structural Mn(IV) (Eq. (2)). The proportion of As(III) oxidized by birnessite over 24 h was doubled in the presence of 5 mM PP in solution compared to the PP-free system (Fig. 1a). In the presence of PP, As(III) oxidation was not significantly promoted over the first 2 h, the apparent rate constant being  $0.1993 \pm 0.0125 \text{ h}^{-1}$  ( $k_3$ , compared to  $k_1 = 0.1804 \pm 0.0349 \text{ h}^{-1}$  - Fig. 1b). Over the next 10 h, As(III) oxidation was highly enhanced in the presence of 5 mM PP, however, with an apparent rate constant of  $0.0438 \pm 0.0101 \text{ h}^{-1}$  ( $k_4$ ). Moreover, addition of PP allowed releasing to solution As species initially adsorbed/precipitated at the birnessite surface (Fig. 1a). Enhancement of As(III) oxidation results from the chelation by PP of Mn(III) formed as the result of Eq. (2) and from the release of these complexes to solution (Eq. (3) - Klewicky and Morgan, 1999):

Previous works showed that the excess of PP relative to Mn(III) should be at least fourfold to prevent the complexes from disproportionating (Qian et al., 2019). Thus, the difference between  $k_4$  and the oxidation rate determined over the subsequent 12 h ( $k_5 = 0.0091 \pm 0.0025 \text{ h}^{-1}$ ) is likely related to the formation of Mn(III) that could not be fully chelated by PP (Fig. 1b).

Mn concentration in solution increased steadily in the presence of PP (Fig. 2a), nevertheless, as shown by the increase in intensity of the 258 nm UV-Vis absorption band (Fig. 2b) that is characteristic of the Mn(III)-PP complex (Soldatova et al., 2017). Consistently, the filtered solution appeared brownish red (Fig. S2), a color typical for Mn(III)-PP (Qian et al., 2019). High-valent Mn in solution, which hereafter refers to Mn(III)-PP, was quantified using Leucoberbelin Blue I (Zhu et al., 2017). The similar increases of aqueous Mn and of Mn(III)-PP indicated that Mn in solution was overwhelmingly trivalent and present as Mn(III)-PP (Fig. 2a), consistent with XANES results (Fig. S3). In the presence of both As(III) and As(V), Mn(III)-PP complexes remained essentially stable over a

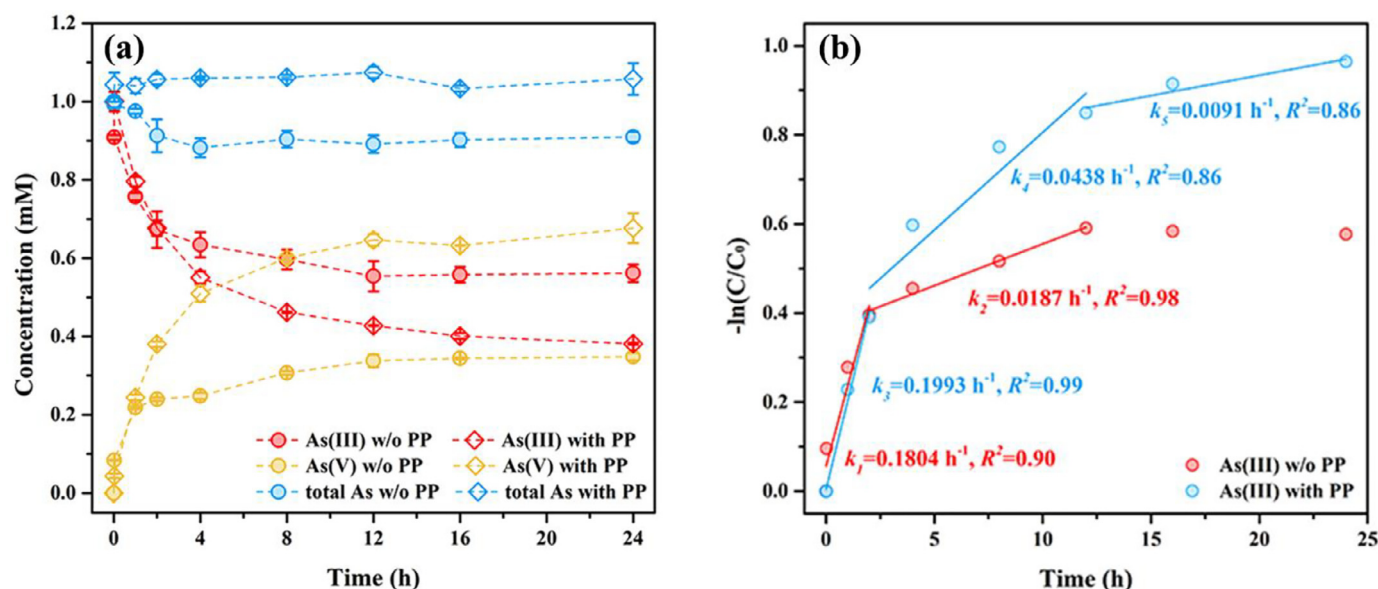

Fig. 1. (a) Evolution of As(III), As(V), and total As concentrations in solution during As(III) oxidation by birnessite in the absence/presence of 5 mM PP (1.0 mM initial As(III) concentration, initial pH 7.2, 24 h). (b) Kinetic analysis of As(III) removal using pseudo-first order model.

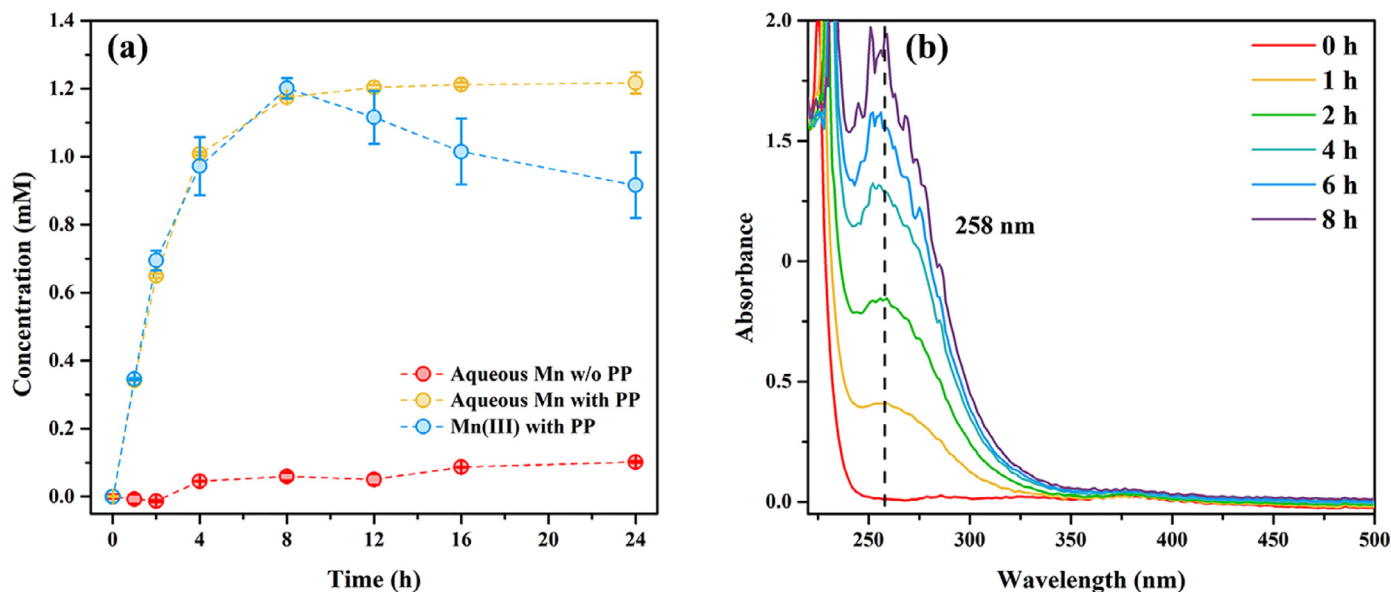

Fig. 2. (a) Evolution of aqueous Mn species concentrations in solution during As(III) oxidation by birnessite in the absence/presence of 5 mM PP (1.0 mM initial As(III) concentration, initial pH 7.2, 24 h). (b) Evolution as a function of reaction time of UV-Vis absorption spectra of the solutions containing Mn(III)-PP as the result of As(III) oxidation experiments (dilution in 1:5 in deionized water) in the presence of birnessite and PP (5 mM PP, 1.0 mM initial As(III) concentration, initial pH 7.2).

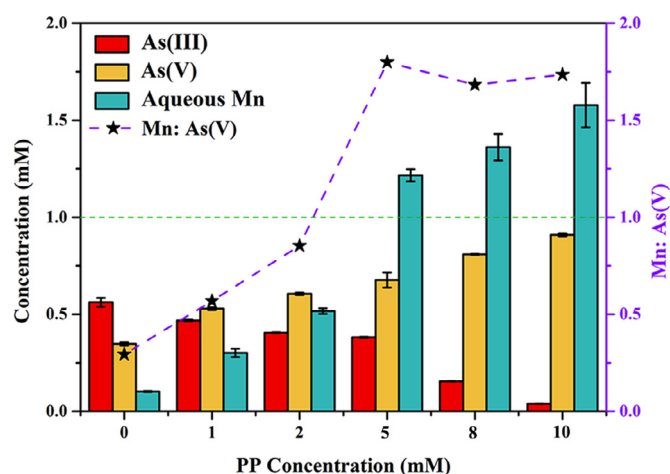

Fig. 3. As(III), As(V), and Mn concentrations in solution and the ratio between Mn and As(V) as a function of the pyrophosphate (PP) concentration for As(III) oxidation experiments in the presence of birnessite (1.0 mM initial As(III) concentration, initial pH 7.2, 24 h).

24 h interval in circum-neutral conditions (Table S1 and Fig. S4), consistent with the slow disproportionation reported for Mn(III)-PP at circum-neutral pH (Qian et al., 2019). The minor decrease of Mn(III)-PP after 12 h is possibly related to Mn oxides catalyzing PP hydrolysis (Wan et al., 2019).

The premise from Eq. (3) was supported by the experimental ratio between As(V), produced from Eq. (1), aqueous Mn(III), produced from Eq. (2) and complexed by PP, that steadily approached a 1:2 ratio with increasing PP in the presence of 0.5 mM As(III) (Fig. S5), consistent with the stoichiometric ratio from Eqs. (1), and (2). At low PP concentration, the experimental ratio was significantly larger than 1:2 due to the limited formation of Mn(III)-PP complexes. Increasing PP concentrations increased Mn(III)-PP concentration in solution, birnessite being essentially dissolved over 24 h in the presence of 10 mM PP and 1 mM As(III) (Fig. 3). The stoichiometric 1:2 ratio between As(V) and Mn indicates that the oxidation of 1 mM As(III) required the consumption of 2 mM

Mn(IV), which exceeded the total Mn content in the suspension. As a result, As(V) in solution never reached 1 mM even in the presence of 10 mM PP.

In addition, time-resolved As K-edge XANES spectroscopy was used to determine the overall relative proportions of As(III) and As(V) in the reaction system (Fig. S6). The position of As K absorption edge steadily shifted to higher energies with increasing reaction time, showing the formation of As(V) at the expense of As(III). Linear combination fitting (LCF) of the spectra unraveled the in-situ evolution kinetics of As(III) and As(V) species. The kinetic of As(III) oxidation using pseudo-first order model was linear over the first 180 min in the presence of PP (apparent rate constant  $k = 0.0049 \pm 0.0001 \text{ h}^{-1}$  - Fig. S7) and of the induced alleviation of surface passivation.

### 3.2. Identification of the solid products

Birnessite synthesized in the present study exhibited a uniform nano-flower morphology resulting from the assemblage of nano-flakes as revealed by FESEM (Fig. 4). When reacted with As(III) in the absence of PP, these nano-flowers appeared "filled" after 24 h of reaction, nano-flake edges becoming blurred, owing to the presence of precipitates at the particle surface. Increasing PP concentration in solution appeared to prevent the presence of these precipitates, leaving clean birnessite surfaces and thus significantly alleviating the passivation of birnessite surface.

SR-XRD patterns of the unreacted birnessite exhibited reflections at 0.723 (not shown), 0.361, 0.244, and 0.142 nm typical for birnessite (Fig. 5a). After reacting with 1 mM As(III) for 24 h in the absence of PP, additional reflections typical for manganite (ICDD#41-1379) were visible (Fig. 5a). Manganite precipitation was consistent with previous reports of birnessite interactions with aqueous Mn(II) at circum-neutral pH (Elzinga, 2011; Lefkowitz et al., 2013; Tournassat et al., 2002). Manganite peaks were not visible when PP was present in the reacting suspension, however (Fig. 5a). None of the various manganese arsenate compounds with contrasting As: Mn molar ratios reported in the literature as secondary products of As(III) oxidation by birnessite (Moore et al., 1990; Tournassat et al., 2002) were detected either

**Fig. 4.** FESEM images of unreacted synthetic birnessite (Bir) and of reaction products from As(III) oxidation experiments in the presence of birnessite (1.0 mM initial As(III) concentration, initial pH 7.2, 24 h). 0mM: absence of pyrophosphate (PP); 2mM: initial PP concentration 2 mM; 5mM: initial PP concentration 5 mM.

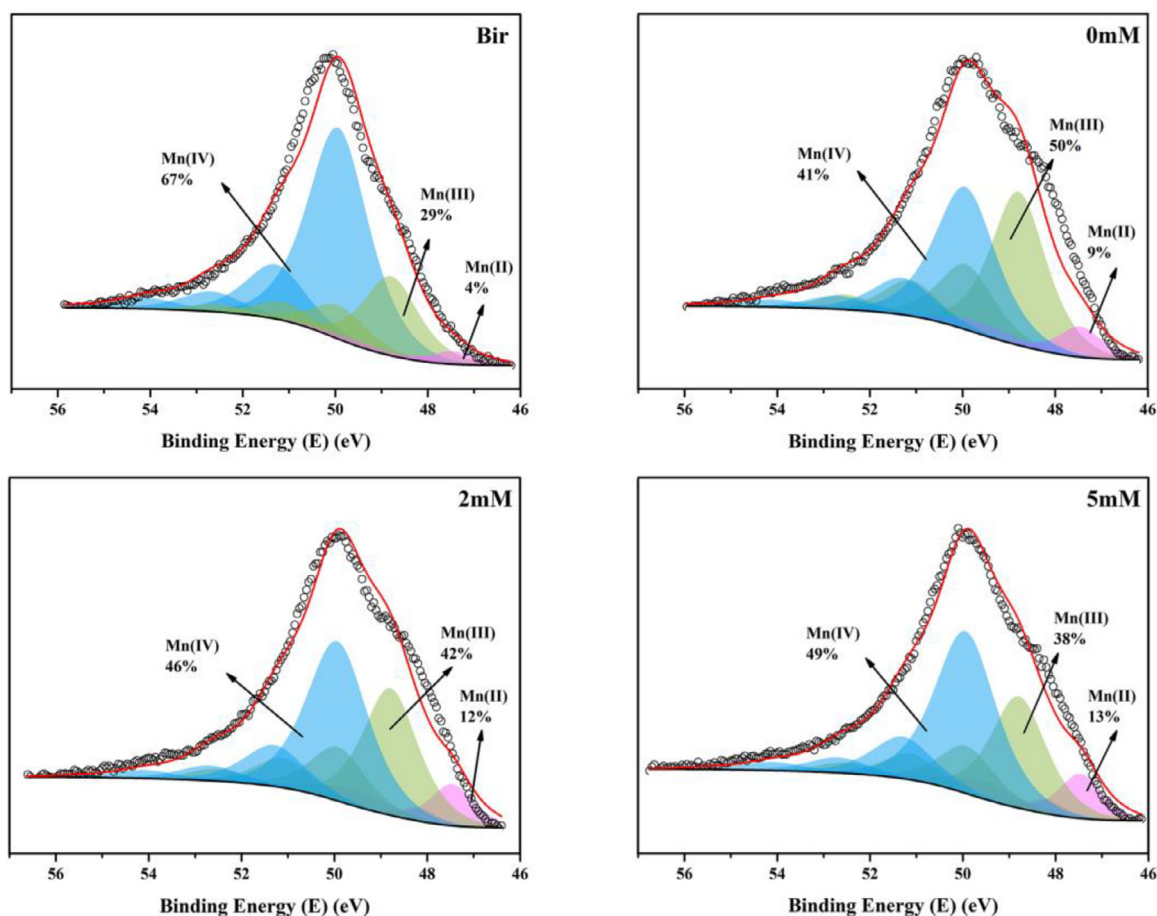

**Fig. 5.** (a) XRD patterns and (b) FT-IR spectra of unreacted birnessite (Bir) and of solid reaction products from As(III) oxidation experiments in the presence of birnessite (1.0 mM initial As(III) concentration, initial pH 7.2, 24 h). 0 mM, 2 mM, and 5 mM labels as in Fig. 4. Ticks at the bottom of (a) indicate the position of manganite reflections (ICDD#41-1379).

in the present study; pyrochroite ( $\text{Mn}(\text{OH})_2$  - ICDD#01-73-1133) was not observed either.

The  $920\text{ cm}^{-1}$  band in the FT-IR spectrum of unreacted birnessite corresponded to the bending vibration of  $-\text{OH}$  located at vacancy sites (Fig. 5b - Yin et al., 2017; Zhao et al., 2012). After reaction with As(III) for 24 h in the absence of PP, new bands were visible at 1150, 1116, and  $1087\text{ cm}^{-1}$  that were related to in-plane and out-of-plane bending modes of structural OH in manganite (Kohler et al., 1997; Lefkowitz et al., 2013), consistent with the presence of this phase shown by XRD data. Consistent with XRD data, these bands, typical for manganite, were not visible when PP was added to the reactive system.

In addition, XPS allowed identifying the chemical state of elements in the few uppermost atomic layers of solids and monitoring the evolution of Mn oxidation state at the birnessite surface.  $\text{Mn}3p$  XPS spectra were fitted using scale factors for the three multiplets used (Table S2) (Ilton et al., 2016), and the relative contributions of the different Mn oxidation states were quantified from the overall multiplet area (Fig. 6) (Table 1). The best fit to  $\text{Mn}3p$  spectrum of unreacted birnessite yielded 67% Mn(IV), 29% Mn(III), and 4% Mn(II), and the relative proportion of Mn(IV) at birnessite surface decreasing to 41% after reaction with As(III) in the absence of PP. Simultaneously, Mn(III) and Mn(II) increased to 50% and 9%, respectively, as the result of As(III) oxidation. The significant increase

**Fig. 6.** XPS spectra ( $Mn3p$ ) of unreacted birnessite (Bir) and of solid reaction products from As(III) oxidation experiments in the presence of birnessite (1.0 mM initial As(III) concentration, initial pH 7.2, 24 h). 0 mM, 2 mM, and 5 mM labels as in Fig. 4.

**Table 1**

Relative proportions of the different Mn oxidation states determined from the fits of  $Mn3p$  XPS spectra shown in Fig. 6.

Samples	Mn (At.%)			AOS
	Mn(IV)	Mn(III)	Mn(II)	
Bir	67	29	4	3.63
0 mM PP1 mM As(III)	41	50	9	3.32
2 mM PP1 mM As(III)	46	42	12	3.34
5 mM PP1 mM As(III)	49	38	13	3.35

of Mn(III) was consistent with the key role played by Mn(IV) in the oxidation of As(III) and with the observed formation of manganite at the particle surface (Figs. 4, 5). If PP was added to the reactive system, the relative content of Mn(III) at the birnessite particle surface decreased (Table 1), consistent with increased proportion of Mn(III)-PP in solution and the absence of manganite formation. Enhancement of As(III) oxidation thus appeared to be induced by the absence of birnessite surface passivation, resulting from manganite precipitation, which was caused by Mn(III) complexation by PP. This enhancement was consistent with theoretical calculations showing the higher affinity of both As(III) and As(V) for Mn(IV) sites compared to Mn(III) sites and with the increased electron transfer rate between As(III) and Mn(IV), compared to Mn(III) (Zhu et al., 2009). Finally, XPS As3d spectra were characteristic of coexisting As(V) and As(III) species (Fig. S8), whose binding energies were  $45.5 \pm 0.1$  eV and  $44.2 \pm 0.1$  eV, respectively (Table S3 – Bang et al., 2005). In the absence of PP, adsorbed/precipitated As

was essentially present as As(V), consistent with previous reports (Fig. S8 – Lafferty et al., 2010b).

### 3.3. The effects of different chelating agents on As(III) oxidation

Naturally occurring organic ligands other than PP, such as oxalate and citrate, are also known to chelate Mn (Duckworth and Sposito, 2005; Jiang et al., 2019; Mu et al., 2018; Taube, 1947; Zhang et al., 2019). As for PP, the presence of oxalate in the reactive system promoted As(III) oxidation (by ~15% after 24 h – Fig. 7a). Fig. 7b showed that little soluble Mn(III) was detected by leucoberberlin blue dye (Zhu et al., 2017), however. The limited enhancement of As(III) oxidation by oxalate was most likely linked to the reduced release of Mn(III) in solution, and thus to the lower ability of oxalate, compared to PP, to prevent surface passivation by chelating Mn(III) formed during the reaction (Eqs. (1), 2; Fig. 7b). The lower chelating activity of oxalate, compared to PP, was consistent with the respective stability constants of these complexing agents with Mn(III) (Log  $K$  are 9.98 and 11.7 for oxalate and PP, respectively) (Nico and Zasoski, 2001). Consistently, the first-order rate constant determined for the breakdown of Mn(III)-oxalate complexes ( $Mn(III)(C_2O_4)^+$ ,  $k = 1.97 \times 10^{-1} s^{-1}$ ) was six orders of magnitude higher than that of Mn(III)-PP ( $Mn(III)HP_2O_5$ ,  $k = 3 \times 10^{-7} s^{-1}$ ) under neutral conditions (Nicholson and Eley, 1997; Taube, 1947; Zhang et al., 2019). Moreover, organic ligands, such as oxalate, are considered as reducing agents interacting with Mn (hydr)oxides (Flynn and Catalano, 2019; Wang et al., 2018; Wang and Stone, 2006). Therefore, the ligands with both low reducing ability (or no redox activity) and high complexation abil-

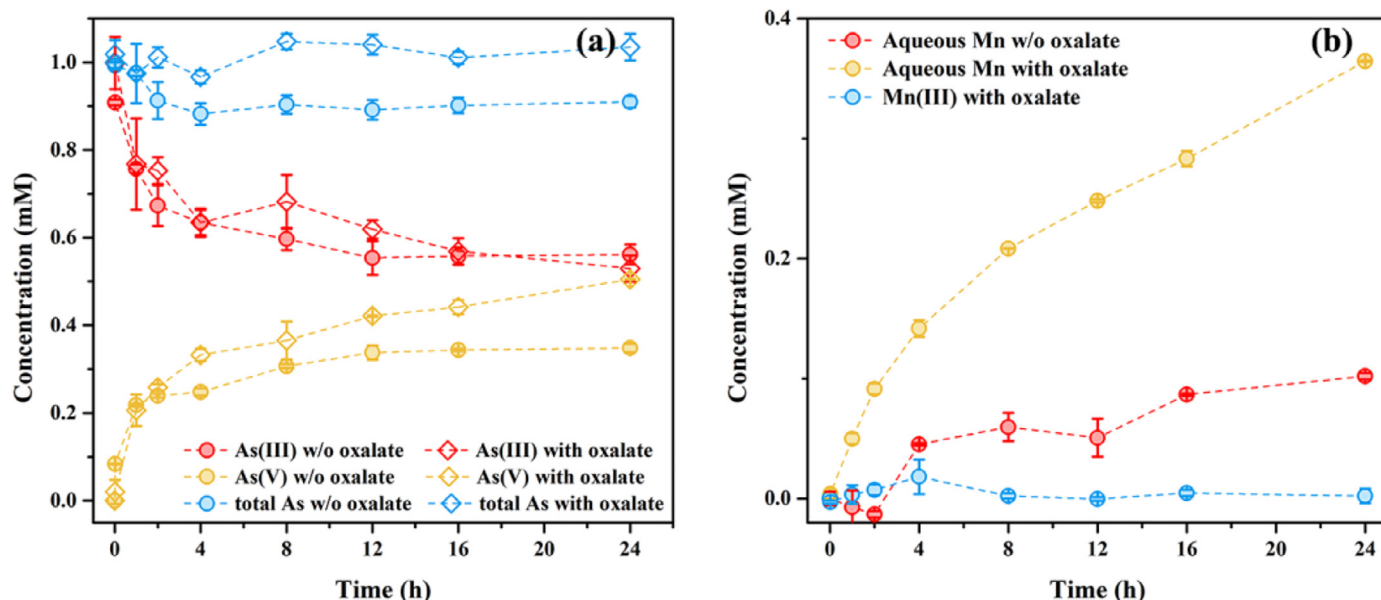

Fig. 7. Evolution of (a) As(III), As(V), and total As concentrations, and of (b) aqueous Mn species concentrations during As(III) oxidation by birnessite in the absence/presence of 5 mM oxalate (1.0 mM initial As(III) concentration, initial pH 7.2, 24 h).

ity with Mn(III), such as PP (Klewicky and Morgan, 1998), appear as ideal inhibitors of Mn(III) (hydr)oxide formation during reaction with As(III).

### 3.4. Environmental significance

Birnessite is ubiquitous in aquatic and terrestrial environments (Butterfield et al., 2013), where As(III) potentially coexists with pyrophosphate (PP). The major source of PP in the environment appears to be ATP released from cells that can be hydrolyzed quickly to produce PP (Orriss et al., 2016). The above results provide a mechanistic understanding for the enhancement of As(III) oxidation by birnessite in the presence of PP through alleviation of surface passivation when the three species coexist.

As(III) oxidation to As(V) is an effective pathway for arsenic detoxification in arsenic-containing drinking and waste water, thus birnessite is a potentially attractive oxidant to be used in large-scale treatment. Previous studies have shown that the presence of aqueous Fe(II) and Mn(II) may inhibit As(III) oxidation by birnessite (Gude et al., 2017), however, as these species are oxidized at the birnessite surface leading to its passivation and favoring As(III) (Ehlert et al., 2014). In the presence of PP, precipitation of Mn(III) on the surface of birnessite will likely be removed, thus alleviating surface passivation and enhancing As(III) oxidation. Hydrous ferric oxides, such as ferrihydrite (Ehlert et al., 2014), formed at the birnessite surface are also likely to be dissolved in the presence of PP (Kassim et al., 1984), thus releasing adsorbed As(III) to solution and promoting its oxidative interaction with birnessite.

## 4. Conclusions

As previously reported, oxidation of As(III) in presence of birnessite and at circum-neutral pH conditions proceeds as a two-electron transfer. The subsequent formation of Mn(III) results from the comproportionation of Mn(II) and Mn(IV) and leads to the precipitation of manganite at the surface of the initial birnessite particles. Manganite precipitation passivates birnessite surface and restrains As(III) oxidation completeness. In the presence of PP, As(III) oxidation is significantly enhanced at circum-neutral pH. The major influence of PP on As(III) oxidation results from its strong chelating

affinity for Mn(III), causing the relative content of Mn(III) at the birnessite surface to decrease. PP chelates newly formed Mn(III) and thus inhibits the formation of solid Mn(III) phases, such as manganite, that may passivate birnessite surface. The addition of PP to the oxidative system has major implications both for the efficiency of As(III) removal during water treatment and for the durability of birnessite as oxidizing catalyzer. Compared to other Mn(III) chelating agents, such as oxalate, pyrophosphate appears especially efficient in impeding surface passivation and limiting possible reductive activity.

### Declaration of Competing Interest

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

### Acknowledgments

This work was supported by National Key R&D Program of China (No. 2017YFD0200201), and the National Natural Science Foundation of China (NSFC Grant Nos. 41471194).
